ABSTRACT

Alzheimer's Disease is one of the most common neurodegenerative disorders. Many efforts have been directed to prevent AD due to its rising prevalence and the lack of an effective curative treatment. Epigenetic changes are involved in regulation of gene expression, and may mediate various pathologies. Epigenetic changes are reversible so that can be easily modulated. Modulation of dysregulated epigenetic mechanisms is a promising therapeutic approach for many diseases. There is some evidence for epigenetic dysregulation at various levels contributing to AD pathogenesis. Despite the recent rapid accumulation of knowledge about AD pathogenesis, the role of epigenetic modifications has not been understood exactly. This chapter provides a brief overview about the role of epigenetic changes that are linked to AD pathogenesis and emerging targets for new therapeutic strategies in this field.

Keywords: Alzheimer's disease, Epigenetic modifications, DNA methylation, Histone acetylation, Sirtuins, MicroRNAs

ABBREVIATIONS

ABCA7	ATP-binding cassette subfamily A, member 7
ACE	angiotensin-converting enzyme

* Corresponding Author's Email: yldz.dincer@gmail.com.

AD	Alzheimer's disease
AGE	advanced glycation endproducts
AICD	APP intracellular domain
anti-TNF- α	antitumor necrosis factor- α
APP	amyloid precursor protein
A β	amyloid β -peptid
BACE1/2	β -site APP cleaving enzyme 1/2
BBB	blood-brain barrier
BIN1	bridging integrator 1
CAT	catalase
CD2AP	CD2-associated protein
COX-1/2	cyclooxygenase-1
CR	calorie restriction
CR-1	complement receptor 1
DNMTs	DNA methyltransferases
ECE-1	endothelin-converting enzyme 1
EPHA1	EPH receptor A1
FOXO	forkhead box protein O
GSK-3 β	Glycogen synthase kinase 3 β
HATs	histone acetyltransferases
HDACs	histone deacetylases
IDE	insulin-degrading enzyme
LEARn	latent early-life associated regulation
LRP1 IL-1 β	interleukin-1 β lipoprotein receptor-related protein 1
MCI	Mild Cognitive Impairment
MDA	malondialdehyde
miRNAs	microRNAs
NAD ⁺	nicotinamide adenine dinucleotide
NCT	nicastatin
NEP	neprilysin
NF- κ B	nuclear factor κ -light chain enhancer of activated B cells
NSAIDs	nonsteroidal anti-inflammatory drugs
PBMCs	peripheral blood mononuclear cells
PICALM	phosphatidylinositol binding clathrin assembly protein
PGC-1 α	peroxisome proliferator-activated reseptor- γ coactivator-1 α
PPAR- γ	peroxisome proliferator-activated reseptor- γ
PS1/2	presenilin 1/2
ROS	reactive oxygen species
SAH	S-adenosylhomocysteine
SAM	S-adenosyl methionine
Sir2	silent information regulator factor 2
SIRTs	sirtuins
SOD	superoxide dismutase
3xTg-AD	triple transgenic animal model of AD
8-OHdG	8-hydroxydeoxyguanosine

1. INTRODUCTION

Alzheimer's disease (AD), originally described by the German neurologist Alois Alzheimer in 1907, is the most common form of dementia in elderly people. AD begins with mild memory loss and then progress with severe cognitive impairment and functional decline. The major pathological hallmarks of AD are accumulation of extracellular amyloid plaques and formation of intracellular neurofibrillary tangles. Amyloid plaques are mainly constituted by amyloid β -peptid ($A\beta$) that occurs primarily in 40mer and 42mer forms. Intracellular neurofibrillary tangles contain hyperphosphorylated tau that is a microtubule-associated protein. Extensive loss of synapses and neurons in the temporal and frontal cortices and hippocampi are also hallmarks of the disease. The pathogenesis of AD is highly complex and involves genetic, epigenetic and physiological alterations in the brain that are still not completely understood. Accumulation of $A\beta$ is neurotoxic and leads to neural, synaptic and cognitive dysfunction. In general, AD can be categorized into two types: early-onset familial AD that is seen in patients younger than 65 years, and late-onset sporadic AD that is seen in patients older than 65 years. Both genetic and environmental factors can contribute to development of these AD forms. Early-onset familial AD constitutes 5% of all AD cases and can be explained genetically by mutations in the amyloid precursor protein (APP) gene or in the genes encoding APP processing enzymes. The late-onset sporadic AD (95% of all AD cases) is likely caused by $A\beta$ overproduction and/or dysfunctions in $A\beta$ solubility or aggregation, endocytosis, degradation, transcytosis and removal [1]. With the increase in life expectancy, the prevalence of AD is going up rapidly worldwide. The number of affected individuals has been estimated as more than 100 million by the year 2050 due to the aging of the population (<http://www.alz.co.uk/research/statistics>, http://www.alz.org/downloads/facts_figures_2012.pdf). Progressive loss of memory and other cognitive functions in AD and the lack of effective treatment options to prevent its progression result in a high burden on social and economic resources. Aging is the greatest risk factor for sporadic forms of AD. However, epidemiological studies indicate that genetic alterations and polymorphisms, abnormal immune or inflammatory responses, low educational level, smoking, physical inactivity, depression, midlife hypertension, high cholesterol level, diabetes, APO ϵ 4 allele positivity, traumatic head injury, oxidative stress, certain drugs and hormone replacement are contributing factors for AD. The disruption of epigenetic mechanisms which control expression of AD-related genes is recently discovered another contributory factor. Despite the tremendous progress within the last a few decades in our understanding of AD pathogenesis, the accurate molecular and epigenetic mechanisms of AD have not been revealed completely.

2. PATHOGENESIS OF ALZHEIMER'S DISEASE

Cellular mechanisms provoking anomalies in AD are still under clarification, but $A\beta$ deposition, hyperphosphorylated tau protein, neuroinflammation, oxidative stress, metal dishomeostasis, mitochondrial dysfunction, certain genetic mutations and presence of APO ϵ 4 allele have been shown to play key role in AD pathogenesis. Two main proteins take play a major role in the pathogenesis of AD: $A\beta$ and tau.

2.1. A β Hypothesis

According to this hypothesis, A β and its aggregates are responsible for neurodegeneration and dementia in AD. A β peptides are natural products of brain metabolism, but the balance between A β production and clearance is disrupted in AD. A β is generated by the proteolytic cleavage of APP which is synthesized in ribosomes on endoplasmic reticulum and then transported to the golgi apparatus. APP is a transmembrane protein which is cleaved by a series of secretases: α then γ , or β then γ for processing. Aberrant cleavage of APP leads to A β overproduction and neuritic plaque formation. Proteolytic processing of APP occurs by one of two pathways, the non-amyloidogenic or the amyloidogenic (Figure 1). For *non-amyloidogenic cleavage* of APP, α -secretase cleaves within the A β encoding region, releasing a soluble fragment, sAPP α , into the extracellular space. sAPP α was shown to have neurotrophic and neuroprotective properties [2]. After this first cleavage the remaining C-terminal fragment which includes 83 amino acid residues (C-83) is subsequently cleaved by γ -secretase within the transmembrane region, generating p3 (A β 17-40) and APP intracellular domain (AICD). AICD and p3 (3 kDa) peptide are released into cytosol and extracellular space, respectively. AICD potentially translocates to the nucleus and functions as a transcription factor [3, 4]. As for *amyloidogenic cleavage*, APP is cleaved by β -secretase and then γ -secretase. β -secretases include β -site APP cleaving enzyme 1 (BACE1) and 2 (BACE2). After the cleavage of APP by β -secretases, sAPP β fragment is released whereas remaining C-terminal fragment of 99 amino acid residues (C-99) is still membrane bound. C-99 is further cleaved by γ -secretase, generating AICD and an insoluble fragment, A β , which contains 38–43 amino acid residues. Several peptides in varying lengths can be generated from the cleavages by β and γ -secretases. Majority of these A β fragments is A β 40. The another fragment, A β 42, is less common but more fibrillogenic. It forms insoluble aggregates. A β accumulation in the brain induces oxidative stress and inflammatory response thus leads to neurotoxicity which contributes to impairment of cognitive functions.

The balance between different secretase activities is very important in the maintenance of the physiologic A β levels. Decreased processing of APP into A β has been found to be correlated with decreased activity of BACE1 [5]. In AD, accumulation of A β has been suggested to occur prior to tau pathology, and A β aggregates may be one of a cascade of pathological events ranging from synaptic dysfunction, oxidative stress, mitochondrial dysfunction, loss of calcium regulation and inflammation leading to tau hyperphosphorylation [6]. It has been thought that increased production of A β and/or decreased degradation by A β -degrading enzymes, or reduced clearance across the blood-brain barrier may cause aggregation and accumulation of A β in the brain. Impairment of synaptic functions and related signaling pathways by A β oligomers result in changes in neuronal activities and cause to release of neurotoxic mediators from glial cells.

The degradation and clearance of A β from the brain has been reported to be impaired in patients with AD. A β clearance happens via transporting across the blood-brain barrier (BBB) and metabolic degradation. A β can be transported across the BBB into the blood or cerebrospinal fluid by low-density lipoprotein receptor-related protein 1 (LRP1) [7], AGE advanced glycation endproducts) receptor, ApoE, and β -2-macroglobulin [8, 9]. ApoE binds extracellular A β and forms ApoE/A β complex which is cleared by low-density lipoprotein receptor-related protein (LRP) via the endosomal/ lysosomal pathway [10]. In vitro and in vivo studies have shown that A β undergoes proteolytic degradation by A β -degrading enzymes such

as neprilysin (NEP), insulin-degrading enzyme (IDE), endothelin-converting enzyme (ECE)-1, angiotensin-converting enzyme (ACE), uPA/ tPA-plasmin system, cathepsin D, gelatinase-A and -B, matrix metalloproteinase-9, coagulation factor XIa, antibody light chain c23.5 and hk14, and α 2-macroglobulin complexes [11]. Thus, both disruption of BBB or decreased activities of these A β -degrading enzymes may contribute to AD pathogenesis.

Figure 1. Processing of beta amyloid precursor protein.

2.2. Tau Hypothesis

Tau is an intracellular protein and belongs to a family of microtubule-associated proteins that normally promotes microtubule assembly and stabilization. Tau protein exerts neurotoxic effects when it is hyperphosphorylated. Hyperphosphorylation causes an impairment in its binding ability with tubulin and subsequently results in loss of its normal function. Hyperphosphorylated tau has reduced capacity to promote microtubule assembly. In addition, hyperphosphorylation promotes its polymerization. It aggregates into filaments itself forming neurofibrillary tangles and causes the disorders known as tauopathies [12]. Abnormal hyperphosphorylation of tau is the key player of AD neurodegeneration as the major component of neurofibrillary tangles in AD. Abnormally hyperphosphorylated tau has been isolated from AD brain in 1990s [13]. In vitro studies have shown that tau phosphorylation at different sites

may cause different effects in its biological function as well in pathogenic role. Phosphorylation of tau at Ser262, Thr231, and Ser235 has been shown to inhibit its binding to microtubules by ~35%, ~25%, and ~10%, respectively [14].

Synaptic loss

Synaptic loss is emerged as an early event in the pathogenesis of AD that is confirmed in rodent brain after acute injection of soluble A β oligomers as well in APP transgenic mouse models [15]. Recent gene array investigations have consistently demonstrated that expression levels of neurotransmitter receptor genes and the genes involved in synaptic vesicle trafficking/release, receptor trafficking, postsynaptic density scaffolding, cell adhesion regulating synaptic stability and neuromodulatory systems are altered in early stage of AD [16-19]. Axonal transport defects, oxidative stress, mitochondrial dysfunction, neuroinflammation and possibly A β accumulation in the brain might result in synaptic loss that is observed in AD patients [20].

2.3. Oxidative Stress in Alzheimer's Disease

Oxidative stress is a state that occurs when there is an imbalance between production and clearance of reactive oxygen species (ROS) such as superoxide anion, hydrogen peroxide and hydroxyl radical. ROS have unpaired electrons in separate orbitals in *their* outer *shell* and exhibit a high reactivity. ROS are produced as a byproduct of the normal oxygen metabolism and they have important role in cell signaling and homeostasis. However, in the case of environmental stress such as UV, ionizing radiation, certain drugs and exposure of certain chemicals ROS levels can increase dramatically causing oxidative stress. Interacting with nucleic acids, proteins and lipids, ROS cause structural and functional defects in these molecules. Transition metal ions such as iron and copper act as pro-oxidant. In the abundant presence of these metal ions, ROS production increases via Fenton and Haber-Weiss reactions. There is consistent evidence for presence of extensive oxidative stress in AD brains [21, 22]. Different studies have revealed that the levels of protein carbonyls and 3-nitrotyrosine (protein oxidation markers), 8-hydroxydeoxyguanosine (8-OHdG) and 8-hydroxyguanosine (DNA and RNA oxidation markers), malondialdehyde (MDA), 4-hydroxynonenal, and F2-isoprostanes (lipid peroxidation markers) are elevated in AD brains [23, 24]. Increased production of hydrogen peroxide and nitric oxide, elevated levels of oxidatively modified proteins and lipids have been shown in transgenic mouse models carrying mutations in APP and presenilin genes (PS1 and PS2) [25].

Increased oxidative stress determined in AD is attributed the pro-oxidant role of A β . A β possesses pro-oxidant properties that has an influence on oxidative processes. At high micromolar and nanomolar concentrations, A β aggregates to form fibrils and induces ROS formation, lipid peroxidation, protein oxidation and DNA damage, and subsequently neuronal death. Transition metals including iron and copper are required for its pro-oxidant activity. Direct interaction between A β and transition metal ions may result in increased ROS formation [26]. In an early study, A β treatment has been shown to increase the levels of hydrogen peroxide and lipid peroxides in cell models [27]. Similar results have also been obtained in animal studies. It has been reported that levels of 4-hydroxy-2-nonenal and isoprostanooids, carbonylic proteins are increased in animal models of AD [28]. On the other hand, as a closed circuit,

oxidative stress also promotes A β production by decreasing α -secretase activity while promoting β - and γ -secretase expression and activity [29].

On the other hand, human organism is equipped with efficient antioxidant defence mechanisms. Harmful effects of ROS can be prevented by antioxidant defence system that is constituted by small antioxidant molecules and antioxidant enzymes such as superoxide dismutase (SOD), catalase (CAT) and glutathione peroxidase. Impaired antioxidant defence is the most important factor for oxidative stress. Defective antioxidant defence, elevated oxidative stress and increased A β deposition have been shown in APP overexpressing transgenic mice [30, 31]. Dumont et al. have demonstrated that facilitation of the mitochondrial antioxidant defence improves resistance to A β , decreases plaque formation or increases plaque degradation in a transgenic AD mouse model [31]. Recently, in accordance with Dumont et al. [31], possible role of SOD in AD has been demonstrated in Tg2576 APP-overexpressing AD mouse model. In this model cytoplasmic copper/zinc superoxide dismutase deletion has been found to be associated with increased A β oligomerization, accelerated loss of memory and spatial learning [32]. Aging is a natural and inevitable process and is associated with an prolonged ROS production. Due to the decline in the normal antioxidant defence mechanisms with aging, human body is insufficient in response to ROS-mediated damage [33]. "Free-radical theory by Harman (1956) [34] proposes that ROS production via aerobic respiration increases with age and causes cumulative damage on cell components during the life time. As respect with the fact that AD is seen in elderly individuals, increased oxidative stress in AD patients may be partially attributed to advanced age.

Oxidative stress may also influence hyperphosphorylation and polymerization of tau. It has been suggested that the elevated amounts of fatty acid oxidation that is demonstrated in AD patients, can facilitate the polymerization of tau [35].

Inflammation is a ROS producing state. Neuroinflammation is a contributory factor for AD that will be described below. Production of ROS by glial cells due to inflammation may exacerbate the oxidative stress in AD patients.

2.4. Metal Dyshomeostasis in Alzheimer's Disease

Metal homeostasis is altered in AD brain. Metal ions such as copper (Cu), zinc (Zn) and iron (Fe) are essential for neuronal function. As respect with the fact that metal dyshomeostasis contributes to oxidative stress, disrupted homeostasis of these metal ions in brain are thought to underlie the pathogenesis of AD [36]. Metal dyshomeostasis in AD has attracted the interest of researchers, and reliable results have been obtained. Copper, zinc and iron trigger signaling cascades that mediate cellular physiology by binding to A β . APP and its A β fragments have specific binding sites for Cu²⁺ ions [37]. In vitro studies have demonstrated that A β -Cu complexes catalytically produce hydrogen peroxide and hydroxyl radical and eventually induce oxidative damage [38]. There is growing evidence that Cu can facilitate A β aggregation by binding to A β which results in A β plaque burden [39].

Iron homeostasis is controlled by transferrin and ferritin. Fe, ferritin and transferrin levels have been found to be altered in the hippocampus and cerebral cortex of AD brains [40]. Iron accumulates within senile plaques and neurofibrillary tangles of AD brains. Excess iron leads to increased production of ROS and finally causes oxidative stress. Oxidation of cellular lipids

and proteins results in synaptic dysfunction whereas oxidative damage to DNA induces apoptotic pathways and neuronal death.

Zinc may accelerate the precipitation of A β and produce protease-resistant "non-structured" aggregates [41]. It has been suggested that compounds affecting zinc homeostasis can decrease A β deposition in the brain [42]. Deregulation of neuronal Zn²⁺ homeostasis is believed to be strictly connected to oxidative stress. Zn²⁺ can trigger ROS production by interfering with the activity of the electron transport chain (inhibits complex I and III) [43, 44].

On the other hand, zinc and iron promote tau phosphorylation and aggregation by binding to tau [45]. In consistent with these data, treatment with metal chelators such as clioquinol and desferrioxamine have provided some success in altering the progression of AD [46, 47]. The development of therapeutic interventions targeted to restore metal balance is an active area of current investigations in the field of AD.

2.5. Mitochondrial Dysfunction in Alzheimer's Disease

Mitochondrial dysfunction plays important role in both brain aging and AD. Structural and metabolic changes have been observed in mitochondria of neurons in AD brain. Mitochondrial dysfunction is an early event in AD. Mitochondrial abnormalities, increased mitochondrial degradation by autophagy, and decreased cytochrome oxidase (complex IV) activity that is associated with increased ROS production have been determined in AD brains [48]. Deficient energy production and impaired metabolic activity have been shown in neurons of AD brain and this situation has been explained by reduction in the number and size of mitochondria [49]. The mitochondria is the major source of ROS in the central nervous system, and is also particularly vulnerable to oxidative stress. Oxidation of mitochondrial DNA renders it vulnerable to somatic mutations which leads to initiation of erroneous APP processing [50]. Moreover, A β deposits can contribute to more mitochondrial damage by disrupting lipid polarity and protein mobility in mitochondrial membranes, and inhibiting key enzymes of the mitochondrial respiratory chain [51, 52].

2.6. Neuroinflammation in Alzheimer's Disease

Neuroinflammation plays a prominent and early role in AD pathogenesis. Neuroinflammation is a response to an inflammatory stimuli comprising over activation of microglia and subsequent over expression of proinflammatory cytokines. Although inflammatory response in AD is useful for restoration of tissue integrity, it becomes harmful when chronically induced. Production of pro-inflammatory cytokines, prostoglandins and ROS increases in chronic inflammatory state which in turn leads to aggravation of A β deposition and induction of neuronal dysfunction. The another link between neuroinflammation and A β deposition is BACE1 that is involved in amyloidogenic processing of APP. BACE1 gene has been shown to have four putative NF κ B binding elements in its promoter region, thus its expression is upregulated upon inflammatory stimuli leading to increased production of A β [53]. Furthermore, the accumulation of A β in plaques may produce sequential inflammatory events and excitotoxicity which in turn cause neurodegeneration and cognitive impairment. Microglia activation has been suggested to occur in mild and early stage of AD pathogenesis.

Vom Berg et al. [54] have demonstrated that suppression of expression and signaling of interleukin-12 and interleukin-23 leads to decreases in microglial activity, A β level and A β plaque burden in a mouse model of AD.

It has been shown that suppression of neuroinflammation is concordant with reduction in A β plaques and hyperphosphorylated tau in brain, and is associated with improvements in cognitive and behavioral deficits in AD mouse models [55, 56]. Piro et al. [57] have reported that genetic inactivation of monoacyl-glycerol lipase, an enzyme that hydrolyzes endocannabinoids to generate the primary arachidonic acid pool for neuroinflammatory prostaglandins, controls arachidonic acid release, reduces neuroinflammation and lowers A β levels and plaques in an AD mouse model of A β deposition.

Due to the role of neuroinflammatory process in AD pathogenesis, reducing neuroinflammation by inflammation-based therapeutic strategies can be used in the prevention and treatment of AD. Nonsteroidal anti-inflammatory drugs (NSAIDs) and peroxisome proliferator-activated receptor- γ (PPAR- γ) agonists have been shown to reduce the expression and activity of β -secretase and lower A β secretion [58]. NSAIDs inhibit the enzymatic activity of cyclooxygenase-1 (COX-1) and inducible COX-2 which catalyze the first committed step in the synthesis of prostaglandins. COX inhibitors can decrease levels of highly amyloidogenic A β 1-42 peptide. Suppression of neuroinflammation with NSAIDs has been suggested to rescue memory and cognitive decline. However, retrospective epidemiological studies have demonstrated that prolonged treatment with NSAIDs delays onset of AD when initiated early stage or before disease initiation [59], but its efficiency has not been shown in neither mild nor moderate forms of AD [60]. On the other hand, treatment with antitumor necrosis factor- α (anti-TNF- α) or interleukin-1 β (IL-1 β) antibodies is efficient in reducing the pathology in animal models [61, 62].

2.7. Mutations and Polymorphisms in Alzheimer's Disease

Mutations in several disease-associated genes such as APP, PS1 and PS2 all of which appear to be involved in APP processing have been shown to cause early-onset autosomal dominant AD [63]. Although it seems unlikely to be significant in late-onset AD susceptibility [64] some investigators have suggested the possibility that the rare variants in these three genes may contribute to the risk for late-onset AD [65]. Heterozygous missense mutations in or near A β -coding exons 16 and 17 are the most frequently detected mutations in APP [66]. Whole-gene duplications [67, 68], rare recessive small deletions [69] and recessive missense mutations [70] have also been identified in early onset AD. These mutations result in altered A β production, changed A β ₄₂/A β ₄₀ ratio and increased fibril formation. Mutations in PS-1 and PS-2 also cause to increased production of more aggregative A β ₄₂ by impairing the γ -secretase-mediated cleavage of APP [71, 72]. Recently large-scale genome-wide association studies have changed the face of the complex genetics of AD, and these data have disclosed the novel findings about the candidate risk genes for the development of AD. According to findings of these studies, single nucleotide polymorphisms in or near complement receptor 1 (CR1), phosphatidylinositol binding clathrin assembly protein (PICALM), bridging integrator 1 (BIN1), CD2-associated protein (CD2AP), CD33, EPH receptor A 1 (EPHA1) and ATP-binding cassette subfamily A, member 7 (ABCA7) may increase the risk for AD by affecting APP processing, A β pathway, synaptic cell functioning, and immune system. [73-75].

Apolipoprotein E (APOE) is a polymorphic glycoprotein which contains 299-amino acid. It is highly expressed in the brain and mainly secreted by astrocytes. APOE exists in three isoforms (E2, E3, and E4) in humans encoded by the APOE epsilon (ϵ)2, ϵ 3 and ϵ 4 related genes [76]. Aside from its well known role as a lipid-transporting entity, APOE is involved in neurogenesis, synaptic integrity, plasticity and repair [77]. Although the APO ϵ 4 allele is represented in approximately 25% of population, it has been postulated to be a risk factor for sporadic AD in older adulthood [78]. The influence of APO ϵ 4-allele on development, progression, clinical presentation of AD and rate of cognitive decline have not been fully described. Cross-sectional studies in patients with AD have shown that the APO ϵ 4 allele is associated with impaired memory function, more severe atrophic changes and hypometabolism in the medial temporal lobe structures [79-82]. Autopsy studies on AD have indicated the APOE ϵ 4 allele to be associated with greater densities of A β deposition, senile plaques and neurofibrillary tangles, especially in the hippocampus [83, 84]. Besides this, the ϵ 2 allele may have a protective effect against AD, and carriers of ϵ 2 allele are associated with less amyloid- β plaques and neurofibrillary tangles than both ϵ 4 carriers and ϵ 3 homozygotes [85, 86].

Although presence of APO ϵ 4 allele has been suggested to be associated with faster cognitive decline by some studies, there are also opposing data. Moreover, some studies have reported a converse effect of APO ϵ 4 on the rate of cognitive decline [87-92]. These contradictory data for the influence of APO ϵ 4 allele on AD development might provide clear support for an antagonistic pleiotrophy hypothesis that the APO ϵ 4 allele confers some cognitive advantage in early life despite adverse consequences in old age [93].

3. EPIGENETIC CHANGES IN ALZHEIMER'S DISEASE

Epigenetic modifications regulate gene expression without altering the DNA sequence. Epigenetic changes are dynamic and unlike genetic mutations, they can be reversed by environmental factors and therapeutics. These modifications that can occur at specific gene loci in specific cells result in specific cellular phenotypes. Environmental factors can induce epigenetic changes in individuals in each period of life and these factors are becoming increasingly relevant with respect to the shift from healthy to diseased state [94]. Physical and behavioral factors, nutrition, lifestyle, physical and mental exercise, environmental pollutants, pesticides, chemicals and certain metals affect the epigenetic mechanisms. Especially, nutrition is one of the main epigenetic regulators. It readily modifies epigenetic pathways. Dietary methyl donors involved in one-carbon metabolism such as folate, vitamin B12, betain, choline and methionine play a pivotal role in DNA methylation as well in maintenance of genomic stability. In addition to their antioxidant properties, dietary polyphenols have been shown to modify the epigenome. There is an overwhelming scientific consensus that epigenetic changes contribute to aging and aging-associated diseases. Recently, the diet containing nutrients that are able to modify epigenetic mechanisms has been suggested as a preventive approach for AD [95].

Studies have indicated that genetic mutations are involved in the pathogenesis of early-onset (familial) AD (around 3% to 5% of cases) but epigenetic mechanisms are likely to be important in the etiology of sporadic form of AD. Epigenetic modulations mediated by DNA methylation, histone modification and non-coding RNAs may explain the complex pathogenic

mechanisms in AD. These mechanisms mediate genome-environment interactions by transforming variable combinations of genetic and environmental factors into long-term adaptive changes in gene expression.

In a recent study, expression of *BACE1* gene has been examined in both triple transgenic animal model of AD (3xTg-AD mice) and peripheral blood mononuclear cells (PBMCs) from patients with AD or Mild Cognitive Impairment (MCI). According to findings of this study; *BACE1* mRNA level is increased in brain of aged 3xTg-AD mice, both in the cortex and hippocampus, the promoter region of the *BACE1* is significantly more acetylated without significant alterations in the promoter accessibility, *BACE1* mRNA level is significantly increased in AD patients whereas it is slightly elevated in MCI patients in comparison to controls subjects. Furthermore, as consistent with a higher transcription rate of the gene, *BACE1* promoter is significantly more accessible in AD patients but chromatin in the *BACE1* promoter is closed in MCI patients [96].

γ -Secretase is a multiprotein complex that is an intramembrane-cleaving protease involved in APP processing. Nicastrin (NCT) is one of the integral components of γ -Secretase and is essential for stabilization of the enzyme [97]. Overexpression of NCT is related with increased A β production [98]. Downregulation of NCT gene has been reported in the brain of aged transgenic mice probably due to nucleosome remodelling which may lead to a decreased accessibility of transcription machinery or hypermethylation of CpG island of the gene promotor [96].

3.1. DNA Methylation

DNA methylation is the first epigenetic modification identified on DNA that regulates gene expression in all known vertebrates. DNA methyltransferases (DNMTs), DNMT1, DNMT2, DNMT3a, DNMT3b, catalyze the transfer of a methyl group to the carbon atom in position 5 of a cytosine moiety of single-stranded DNA in the presence of the methyl donor S-adenosyl methionine (SAM) [99, 100]. DNMT3a and 3b fall in the group of de novo methyltransferases (they methylate previously unmethylated CpG sequences), while DNMT1 copies the preexisting methylation marks onto the new strand during replication [101]. SAM is derived from one-carbon metabolism which is regulated by availability of folate, vitamin B12 and vitamin B6. In promoter regions, DNA methylation occurs on the 5' position of cytosine residue in CpG rich regions called CpG islands. Methylation at this site disrupts the binding of transcription factors and recruitment of methyl-CpG-binding domain proteins that are associated with chromatin compaction and gene silencing. On the contrary, methylation within the body of the gene usually marks active transcription [102]. Recently it has been discovered that methylated cytosine (5mC) can be further hydroxylated, predominantly in brain tissue. This reaction is mediated by the TET proteins family. 5-hydroxymethylcytosine (5hmC) formation is suggested as a potential mechanism leading to DNA demethylation [103].

Studies with monozygotic twin siblings who had spent a long period of their lives apart have demonstrated that extrinsic factors derived from environmental exposure affect DNA methylation patterns [104]. DNA methylation may be affected by aging, deficiencies of vitamin B12, B6 and folic acid, oxidative stress, pesticides and heavy metal exposure. Some of these factors such as arsenic, cadmium, lead and pesticides interfere with the regulation of DNMTs

[105]. Others such as deficiencies of vitamin B12, B6 and folic acid influence DNA methylation patterns altering SAM availability via metabolites of the SAM cycle (Figure 2).

Figure 2. SAM cycle.

5-methyltetrahydrofolate donates its methyl group to homocysteine (HCY) and converts it to methionine in a reaction which requires vitamin B12. Then methionine is converted to SAM. SAM is thereby converted to S-adenosylhomocysteine (SAH), which in turn is converted to HCY in a reversible reaction. SAM level has been demonstrated to be decreased in post mortem AD brain, and increased HCY has been suggested as a risk factor for AD [106]. The lower availability of SAM can be related to the altered expression of genes involved in APP metabolism and A β accumulation.

Normal aging involves the gradual decline in memory and cognitive functions that are correlated with a profound changes (global DNA hypomethylation and hypermethylation of CpG islands) in DNA methylation [107]. DNA methylation modifications can be divided into two groups in AD: global DNA methylation modifications and gene-specific DNA methylation modifications [108]. Genomic and sequence-specific DNA methylation patterns are distinct between different brain areas. In 2010 Mastroeni et al. [109] have demonstrated that global DNA and RNA methylation status in entorhinal cortex layer II neurons are significantly diminished in AD. In accordance with this data, 5mC and 5hmC levels have been found to be decreased in hippocampus of AD patients [110]. Recently, DNA hypomethylation has been demonstrated to be correlated with a greater amyloid plaque burden, enhanced APP production, and increased activities of BACE-1 and PS1 [110, 111]. On the other hand, DNA hypermethylation is also present in AD. A postmortem human frontal cortex study has shown the presence of DNA hypermethylation in AD cases [112]. Evidence from genetic and immunohistochemical studies on AD cases supports the notion that aberrant DNA methylation modification of a number of specific genes, which are believed to be related to AD, can

contribute to onset and progression of the disease. In this context, APP gene has been investigated as a primary target.

APP Gene

In an early study, Toghi et al. (1999) [113] have reported the hypomethylation in APP promoter in aged brain, which would be consistent with an increase in APP expression with aging. Afterwards, methylation status of different regions of APP promoter has been examined in AD by Barrachina and Ferrer, (2009) [114], and no significant difference has been found between control and disease samples obtained from frontal cortex and hippocampi of postmortem brains in various stages of AD. They have concluded that small changes in methylation of DNA promoters in vulnerable cells might have not been detected in total homogenates [114].

BACE, PS1 and DNMT Genes

According to findings of in vitro studies, BACE and PS1 genes are regulated by methylation. The reduction of folate and vitamin B12 in culture medium can cause a decrease in SAM concentration with subsequent increase in PS1 and BACE levels and an increase in A β formation [115-117]. Most recently, the methylation status of PS-1, BACE1, DNMT1, DNMT3A and DNMT3B promoters in blood DNA obtained from AD patients and controls have been analysed. It has been found that none of the studied regions is differently methylated between AD and controls [118].

Neprilysin (NEP)

NEP is one of the enzymes involved in A β degradation. Its expression is decreased in both AD and aged brains. Promoter region for NEP has been found to be hypermethylated in murine cerebral endothelial cells model. It has been concluded that hypermethylation of NEP promoter suppresses NEP's expression at mRNA and protein levels, which in turn causes to increased A β accumulation [119].

Some other genes that are thought to be involved in AD pathogenesis have also been investigated in respect with the promoter methylation status. The promoters for *cAMP-responsive element* that is associated with synaptic plasticity have been found to be hypermethylated in AD [112]. *Glycogen synthase kinase 3 β* (GSK3 β) is the major kinase that phosphorylates tau protein in brain. It has been reported that GSK3 β activity and expression levels are increased in AD brains which may be due to hypomethylation of its promoter region [120]. Promoter methylation of *Neuronal protein phosphatase 2A* has been found to be downregulated in affected brain regions of AD patients, causing the accumulation of both phosphorylated tau and APP isoforms, and increased secretion of A β peptides [121, 122]. Promoters of *cyclooxygenase-2*, *brain-derived neurotrophic factor* and *NF- κ B* have been reported to be hypomethylated, whereas promoters of *cAMP response element-binding protein* and *synaptophysin* have been reported to be hypermethylated in frontal cortex of postmortem AD brain [112].

3.2. Histone Modifications

Reversible post-translational modifications such as phosphorylation, acetylation, methylation, glycosylation and ubiquitination modulate biological activity of proteins [123]. In recent years, protein acetylation at the lysine ϵ -amino group has gained considerable interest due to its ability to regulate important cellular processes. Modifications in histone proteins may alter the access of the transcriptional machinery to genes in DNA. Acetylation of histone tails is the most frequently studied and best defined histone modification. Addition of an acetyl group from acetyl-coenzyme A to lysine residues on the N-terminus that protrudes from the surface of the nucleosome which is named as "histone tail" is accomplished by histone acetyltransferases (HATs). Removal of these acetyl groups from histone tails is catalyzed by histone deacetylases (HDACs) [124]. Acetylation of histone tails neutralizes their positive charge and decreases the interaction between histone tails and negatively charged phosphate groups of DNA backbone. This conformational relaxation enhances accessibility of the gene for transcription machinery. On the contrary, deacetylation of histone tails produces a more condensed chromatin and results in gene silencing. HDACs are classified into four classes as I, II, III and IV according to their sequence homology. Class I, II and IV HDACs are Zn-dependent whereas class III HDACs that are called as sirtuins are nicotinamide adenine dinucleotide (NAD⁺)-dependent.

HDAC2 is a class I HDAC that is suggested to negatively regulate memory and synaptic plasticity in healthy mouse brain. The protein level of HDAC2 in AD mouse models and also in postmortem brain tissues of AD have been found to be increased along with cognitive impairment [125]. After the discovery of the fact that histone acetylation vigorously participates to activity-dependent neural plasticity via regulation of critical gene transcription, inhibition of histone acetylation has been investigated in mouse models of AD. In the study conducted by Francis et al. acetylation level of hippocampal histone 4 (H4) in APP/PS1 double mutant transgenic mice has been found to be 50% lower than in wild-type littermates, and this has been linked with impairment in associative learning that is observed in the transgenic mice. Acute administration of HDAC inhibitor, trichostatin A, has rescued the deficiency in H4 acetylation and increased associative memory formation in APP/PS1 mice [126]. Ricobaraza et al. (2009) [127] have demonstrated that intra-perinatal injection of phenylbutyrate (a HDAC inhibitor) improves spatial memory consolidation in 16 month-old Tg2576 mice. This study has not reported a change in amyloid pathology, but rather determined a reduction in pathological phospho-tau levels. In another study, phenylbutyrate treatment has been shown to rescue decreased hippocampal H4 acetylation and impaired dendritic spine density [127, 128]. Notably, these studies have demonstrated that HDAC inhibitors are effective just after the onset of disease. In the case of advanced stage of disease progression, prolonged treatment with sodium butyrate has shown to improve associative memory in APPPS1-21 mice even when administered at a very advanced stage of pathology. The recovery of memory function has been found to be associated with elevated hippocampal histone acetylation and increased expression of genes implicated in associative learning [129]. Recently, orally administrated MS-275 (Entinostat), a class I HDAC inhibitor, has been shown to improve behavioral impairment, reduce neuroinflammation and amyloid plaque deposition in hippocampus and cortical regions of APPPS1-21 mice [130]. Taken together, HDAC inhibitors reduce amyloid plaque deposition, possibly by regulating expression of enzymes that control A β processing and clearance [131].

There are some evidence for the potential role of A β on histone acetylation. Lithner et al., 2013 [132] have reported that treatment with A β oligomers results in increased levels of acetylated H3K14 and loss of dendritic spines in cortical/hippocampal cultures. Further studies are needed to reveal causative interaction between A β and histone modifications.

HDAC6 is a member of class II HDAC and is primarily localized in the cytoplasm. By modifying acetylation levels of α -tubulin and cortactin, an F-actin-binding protein, HDAC6 regulates microtubule-dependent and actin-dependent cell motility. HDAC6 is suggested as a potential modulator of tau phosphorylation and accumulation. Ding et al. [133] have demonstrated *in vitro* and *in vivo* that HDAC6 co-localizes with tau in hippocampus of AD brain; selective inhibition of tubulin deacetylation activity of HDAC6 by tubacin does not disrupt HDAC6-tau interaction but decreases site-specific tau phosphorylation (at Thr231); protein level of HDAC6 is elevated in cortex and hippocampus of postmortem AD brain as compared to those in young normal brain.

First identified in *saccharomyces cerevisiae*, sirtuins which stands for silent information regulator factor 2 (Sir2), is grouped as class III HDACs. NAD⁺ is required for sirtuin activity [134]. Not only histones but also non-histone proteins such as transcription factors, metabolic and apoptotic modulators are the target for sirtuins. Sirtuins are highly conserved from prokaryotes to humans, the sirtuin family comprises seven homologs (SIRT1-7) in mammals. They differ from each other according to their tissue specificity, cellular localization, expression patterns, enzymatic activity and substrates [135]. SIRT1, SIRT6 and SIRT7 are nuclear proteins. SIRT1 shuttles between nucleus and cytoplasm. SIRT2 is predominantly localized in cytoplasm [136]. SIRT3, SIRT4 and SIRT5 are mitochondrial proteins. Recent findings suggest that localization of SIRT3 changes from the mitochondria to the nucleus, when SIRT3 and SIRT5 are co-expressed [137]. Certain sirtuins have also mono-ADP-ribosyl transferase activity. SIRT4 and SIRT6 have weak deacetylase activity but they are able to transfer ADP-ribosyl group to their substrates [138]. SIRT5 was identified as a lysine demalonylase and desuccinylase [139].

In early 2000s, epidemiological studies have revealed that individuals who maintain a low calorie diet have a reduced risk of developing AD. The influence of calorie restriction (CR) on AD pathology has been examined in AD mouse models, and it has been shown that CR reduces amyloid plaques by activating SIRT1 [140, 141]. Neuroprotective effect of CR has been attributed to increase in NAD⁺/NADH ratio and subsequent activation of SIRT1 during the CR. SIRT1 is the most frequently studied sirtuin in AD. It is highly expressed in certain brain regions including cortex, hippocampus, cerebellum and hypothalamus. Non-histone substrates of SIRT1 are core RNA polymerase I transcriptional machinery, HAT p300/CBP [142], tumor suppressors p53 and p73 [143, 144], nuclear factor κ -light chain enhancer of activated B cells (NF- κ B) [145], forkhead box protein O (FOXO) family of transcription factors [146] and peroxisome proliferator-activated receptor γ (PPAR γ) coactivator-1 α (PGC-1 α) [147]. All of these molecules are involved in regulation of neurogenesis, mitochondrial biogenesis, apoptosis and antioxidant defence in the brain. SIRT1 inhibits p53 and NF- κ B and consequently reduces their pro-apoptotic and pro-inflammatory effects, respectively. SIRT1 may be involved in neuroprotection due to its inhibitor effect on p53-mediated apoptosis and upregulating role in α -secretase production [148]. According to results of studies with cell culture models and transgenic mouse models, SIRT1 overexpression increases α -secretase activity, reduces A β formation, promotes neuronal survival, and is neuroprotective against A β toxicity [141, 149, 150]. SIRT1 deacetylates retinoic acid receptor and activates transcription of ADAM10 which

encodes α -secretase. Since α -secretase is responsible for non-amyloidogenic cleavage of APP, upregulation of α -secretase shifts APP processing to reduce the pathological accumulation of toxic A β peptides [149].

There is some evidence for beneficial effect of SIRT1 activation on taupathy. It has been demonstrated that breakdown of tau is inhibited when tau is acetylated by histone acetyltransferase p300. SIRT1 deacetylates the acetylated tau and promotes its degradation and clearance. SIRT1 downregulation has been shown to inhibit tau polyubiquitination and tau turnover, thus results in accumulation of phospho-tau [151]. Recently Du et al., 2014 [152] have demonstrated that activation of SIRT1 attenuates cerebral ventricular streptozotocin-induced tau hyperphosphorylation and cognitive injuries in rat hippocampi.

Metabolic regulator role of SIRT1 is well documented. SIRT1 controls metabolic processes by activating PGC-1 α , a master regulator of mitochondrial biogenesis. PGC-1 α activation results in increased insulin sensitivity and inhibition of mitochondrial dysfunction. In this context, SIRT1 can mediate neuroprotection [153]. As another neuroprotective mechanism, SIRT1 induces basal rate of autophagy which is an important way for the removal of toxic misfolded protein aggregates such as A β [154].

Julien et al. [155] have reported that cortical SIRT1 expression is decreased in autopsy specimens of AD patients but not in the individuals with MCI; SIRT1 mRNA and protein levels are negatively correlated with the duration of symptoms and the accumulation of tau, but are weakly correlated with the A β 42. In accordance with these data, a significant decline in serum SIRT1 level has been determined in patients with both AD and MCI in comparison to healthy elderly individuals [156].

Taken together, SIRT1 activation seems as a useful approach to prevent onset and progression of AD, thus has gained great interest. Resveratrol is a naturally occurring polyphenol found in red grapes and red wine. It is known with its antioxidant, anti-carcinogenic and anti-inflammatory activities. In addition to these properties it is a powerful activator of SIRT1 [157]. SIRT1 activation by resveratrol has been shown to protect against polyglutamine toxicity [158] and plaque formation in AD models. Also, it may prevent apoptotic death of neurons by deacetylating and subsequently repressing p53 activity [159]. Therapeutic role of resveratrol in AD has been extensively investigated. In transgenic mouse model of AD, resveratrol has been shown to prevent learning impairment by increasing deacetylation of PGC-1 α and p53 [160]. In addition, resveratrol has been demonstrated to inhibit amyloid burden by increasing mitochondrial complex IV protein levels in mouse model of AD [161]. Resveratrol is undergoing evaluation in clinical trials (www.clinicaltrials.gov).

SIRT3 is a mitochondrial protein. SIRT3 decreases mitochondrial membrane potential and production of ROS [162]. SIRT3 has been thought to be involved in neuroprotection. Because deacetylation activity of SIRT3 may protect neurons via decreasing ROS levels or increasing O₂ consumption in mitochondria [163].

In addition to histone acetylation, dysregulation of histone methylation has also been suggested to be related to synaptic plasticity and cognition [164, 165].

3.3. MicroRNAs

MicroRNAs (miRNAs) are small non-coding RNAs (21-25 nucleotides in length) and regulate gene expression post-transcriptionally. miRNAs bind to target mRNAs at their 3'-

untranslated regions and suppress their translation and/or promote their degradation [166]. More than 30,000 miRNAs have been identified in humans. As indicated by a large number of studies in the last decade, miRNAs play an important role in various processes such as proliferation, differentiation and apoptosis in both healthy and pathological states [167]. miRNAs can be used as potential diagnostic tools for many diseases due to their stability and convenience of detection in serum. The finding that specific circulating miRNAs are altered in plasma and serum of cancer patients has opened the door to novel diagnostic and possibly therapeutic tools for AD.

Orchestrating the changes in gene expression and protein production, miRNAs take place in memory consolidation and contribute to pathogenesis of neurodegenerative diseases. miRNAs are highly expressed in different neuronal compartments of the brain, and many of them are brain-specific or brain-enriched [167]. miRNAs have selective distribution within neurons and synapses. They have been found to regulate translation of proteins needed for neurite outgrowth, synaptogenesis and activity-driven synaptic plasticity [168-170]. They may also orchestrate fine-tuning of gene expression required for learning, memory and cognitive performance in general.

A number of miRNAs have been strongly implicated in AD, particularly brain-enriched or brain-specific miRNAs. Identifying deregulated miRNAs, miRNA profiling studies have opened a new area for researches in the field of AD. A number of specific miRNAs have been determined to be dysregulated in patients with AD. These specific miRNAs may affect the AD-related pathology either directly (via APP and BACE1), or indirectly by affecting genes related with neurogenesis and immune response [171-173]. In vitro studies have revealed that miR-106a, -520c [174], members of the miR-20a family, such as -20a, -106a/b and -17 [175], miR-16 and -101 [176, 177] and most recently miR-147, -655, -323-3p and -153 [178] directly regulate APP.

On the other hand, A β is a powerful regulator of miRNA levels. Schonrock et al. [179] have found that A β leads to a severe change in miRNA profiles; incubation of primary hippocampal neurons with A β 42 preparation causes to down-regulation of substantial proportion of miRNAs (miR-9, -181c, -148b, -30c, -20b, -361, -21, 409-3p and Let-71).

The expression of certain miRNAs changes over time, supporting the transient effect on miRNA expression during AD development. Loss of miRNA cluster containing miR-29a, -29b1 and -9 in sporadic forms of AD has been found to correlate with increased BACE1 expression and increased A β levels [172]. In an in vitro study, the level of BACE1 has been found to be down-regulated in mice overexpressing miR-29c and it has been concluded that miR-29c might be an endogenous BACE1 regulator [180]. Animal studies have indicated an inverse correlation between BACE1 protein level and miR-298, -328 [181], -103 and -107 [182].

Previous evidence of post-mortem AD brains and serum samples have demonstrated a dysregulation in a number of miRNAs, including miR-9, miR-29a, miR-29b, miR-101, miR-106, miR-125b, miR-181c, miR-137 and miR-125b that are potentially contribute to increased APP expression and A β production [171, 172, 183-187].

4. FUTURE PERSPECTIVES

There is strong evidence that epigenetic alterations are inextricably linked with several major pathological processes in AD. Pathological alterations finally leading the AD are established very early in life. This can be explained by latent early-life associated regulation (LEARn) model. According to this model various environmental factors including diet, are associated genes in a long-term fashion, beginning at early developmental stages. These modifications that do not have pathological consequences until later in life are mediated by epigenetic alterations in the promoter regions of genes [188]. Regardless a cause or consequence, epigenetic dysregulations are an important factor contributing to development of AD. Unlike DNA mutations, epigenetic disruptions are potentially reversible and therefore provide an important target for pharmacological intervention. The possibility of transgenic animal models of AD has facilitated to search the role of epigenetic mechanisms on disease-related pathologies such as A β and tau. Some epigenetic changes occur long before the appearance of AD symptoms. If such changes are identified and detected early, it could be possible to prevent onset of AD via epigenetic therapeutic approaches. Despite the intense investigation in this field previous findings are not enough for approval of epigenetic drugs in AD. DNA methylation alterations in promoter of AD-related genes should be better understood. Further researches are needed to reveal DNA methylation changes affecting the transcription of AD-related genes, particularly effect of demethylation on hypermethylated gene promoters should be examined in AD models. SIRT1 is frequently studied but not much is known about the role of other sirtuins in AD. Other sirtuins, particularly SIRT2 and SIRT3 also seem to play a role in AD. It would be interesting to see whether other sirtuins have an effect in AD pathogenesis. Recently, SIRT1 activators have become a novel target for AD management and are undergoing evaluation in clinical trials. miRNAs are promising molecular tools to identify main pathways implicated in different aspects of the disease such as accumulation of A β , hyperphosphorylation of tau, neuroinflammation and neuronal cell death. Accumulating evidence suggests that alterations in the miRNA profiles of brain contribute to AD pathogenesis. Thus, understanding of miRNA-mediated gene silencing which contributes to AD pathogenesis provides a new perspective in AD management.

ABSTRACT

Cardiovascular disease (CVD) is not a single condition, but an umbrella term used to describe a range of common diseases affecting the heart and the circulatory system. The term commonly includes diseases of the cardiac muscle and of the vascular system supplying the heart, brain, and other vital organs. Many of these conditions can be life-threatening. CVD is the leading cause of death in the world, affecting all populations, irrespective of demographic or socioeconomic differences and is responsible for one third of all deaths.

In the present chapter, we focus on the epigenetic control of embryonic cardiac development and the role of epigenetic mechanisms in CVD observed from results in human, animal and cell culture studies' approaches. We discuss the main epigenetic mechanisms involved in heart development and major CVDs such as coronary heart disease (CHD), heart failure (HF), myocardial infarction (MI), hypertension, stroke, arrhythmias, cardiomyopathy and cardiac hypertrophy (CH). Additionally, this chapter also focuses on the epigenetic modifiers that are involved in the development of CVD, and the potential utility of epigenetics-based therapeutic strategies in CVD.

Keywords: epigenetic, cardiovascular disease, coronary heart disease, heart, post-translational modification

ABBREVIATIONS

11 β HSD2	11 β -hydroxysteroid dehydrogenase 2
5-azaC	5-azacytidine
5hmC	5-hydroxy-methylcytosine
5mC	Methylation of cytosine
AMOTL2	Angiomotin like protein-2
ANF	Atrial natriuretic factor
ANRIL	Antisense non-coding RNA in the <i>INK4</i> locus
ARH	
GAP24	Rho-GTPase activating protein-24
AT1bR	Angiotensin type 1b receptor
BAF	BRG1-associated factor
BNP	Brain Natriuretic Peptide
BRG1	Brahma-related gene-1
BRM	Brahma
Bvht	Braveheart
CARD8	Caspase recruitment domain 8
Cbp	Creb-binding protein
CH	Cardiac hypertrophy
CHD	Coronary heart disease
CHD7	Chromodomain helicase DNA-binding 7
COL15A1	Collagen type XV A1
CRB	CREB binding protein
CVD	Cardiovascular disease
CYP1A1	Cytochrome P450A1
DAC	5-aza-2-deoxycytidine
DGCR8	DiGeorge syndrome critical region gene 8
DNMT	DNA methyltransferase
DOT1L	DOT1-Like Histone H3K79 Methyltransferase
DOT1L	Telomeric silencing-1-like
EGFR	Epidermal growth factor receptor
ENaC	Epithelial sodium channel
ER	Estrogen receptor
ESC	Embryonic stem cell
F2RL3	Coagulation factor II (thrombin) receptor-like 3
Fendrr	Foxf1 adjacent non-coding developmental regulatory RNA
Gata4	GATA binding protein 4
GR	Glucocorticoid
H3K4	Histone H3 lysine 4
HAND1	Heart and neural crest derivatives expressed 1

HAT	Histone acetyltransferase
Hcy	Homocysteine
HDAC	Histone deacetylase
HF	Heart failure
HHcy	Hyperhomocysteinemia
IL	Interleukin
lncRNA	Long non-coding RNA
Irx4	Iroquois homeobox 4
IUGR	Intrauterine growth restriction
Jarid2	Jumonji AT rich interactive domain 2
KDM1A	Lysine-specific histone demethylase 1A
LINE-1	Long interspersed nucleotide elements-1
LIPCAR	Long intergenic noncoding RNA predicting cardiac remodeling
LSD-1	Lysine (K)-specific demethylase 1A
MBD	Methyl-CpG binding domain protein
MeCP2	Methyl-CpG-binding protein 2
MED13	Mediator complex subunit 13
MEF2C	Myocyte enhancer factor 2C
MHC	Myosin heavy chain
MI	Myocardial infarction
MIAT	Myocardial infarction-associated lncRNA transcript
MiRNA	MicroRNA
MLC2V	Myosin light chain 2 ventricular
Msx2	Msh homeobox 2
MyoD	Myogenic differentiation
NAD	Nicotinamide adenine dinucleotide
NF- κ B	Nuclear factor- κ B
NKCC1	Na ⁺ /K ⁺ /2Cl ⁻ cotransporter 1
PBAF	Polybromo-associated BAF
PBMC	Peripheral blood mononuclear cell
PPAR	Peroxisome proliferator-activated receptor
PRC2	Polycomb silencing complex 2
RNAPII	RNA polymerase II
ROS	Reactive oxygen species
RXR α	Retinoid X receptor-alpha
sACE	Somatic angiotensin-converting enzyme
SAM	S-adenosylmethionine
SMC	Smooth muscle cell
SMYD1	SET and mynd domain containing 1
SRF	Serum response factor
SWI/SNF	SWItch/Sucrose non-fermentable
TET	Ten-eleven translocation
TNF	Tumor necrosis factor
VANGL2	Van Gogh-like 2
VDR	Vitamin D Receptor
VSMC	Vascular smooth muscle cell

1. EPIGENETIC MECHANISMS

Epigenetics refers to genetic factors that change the phenotype of an organism or the biological functions without changing the DNA sequence. DNA base modifications, post-translational modifications of histone proteins, and RNA-based mechanisms are major processes involved in epigenetics.

Among the epigenetic factors, methylation of cytosine (5mC) bases within the DNA is the essential pathway by which DNA is modified that is relevant for epigenetic changes. DNA methylation usually occurs within the context of CpG dinucleotide sequences (CpG-sites) [1]. The main function of DNA methylation is to modulate the expression of the genetic information by modifying the accessibility of DNA to the transcription binding factors. DNA methylation plays a key role in X-chromosome inactivation, genomic imprinting, and tissue-restricted gene expression during development and differentiation [2]. The process of DNA methylation is conducted by enzymes called DNA methyltransferases (DNMTs) [1]. Methylation in DNA can be actively removed through oxidative demethylation by the Ten-eleven translocation (TET) family (TET1, TET2 and TET3) [3]. TET protein family is involved in oxidizing of 5mC to 5-hydroxymethylcytosine (5hmC). 5hmC is another important epigenetic modification on DNA in mammalian cells.

Although histones are the proteins that make up nucleosomes, the post-translational modifications of these proteins are another epigenetic mechanism affecting gene expression. “Histone Code Hypothesis” proposes that various combinations of histone modifications may control chromatin structure and transcriptional status. Among histone modifications defined by the histone code, the acetylation, methylation and phosphorylation are important mechanisms of epigenetic regulation [4]. Histone acetylation is catalyzed by proteins known as histone acetyltransferases (HATs) and histone deacetylation is carried out by histone deacetylases (HDACs) [5]. Similarly, histone methylation is regulated by histone methyltransferases and histone demethylases. Histone phosphorylation is also catalyzed by several distinct kinases that are mostly specific for individual histone residues [6].

RNA-based mechanisms are the most recently defined of the three major types of epigenetic regulation. RNA-based mechanisms exclusively focus on microRNAs (miRNAs), short non-coding RNAs, which modulates post-transcriptional repression of epigenetic regulators of gene expression. MiRNAs are endogenously produced RNA molecules that are approximately 22 nucleotides in length. At least 30% of human genes are thought to be regulated by miRNAs [7]. MiRNAs are transcribed by miRNA genes in a primary transcript (pri-miRNA). Drosha-DGCR8 complex processes pri-miRNA as precursor-miRNAs (pre-miRNAs) in the nucleus. Pre-miRNAs are transported into the cytosol where Dicer cleaves the pre-miRNAs to generate a short double-stranded miRNA-miRNA duplex [8, 9]. Mature miRNA targets to complementary mRNA sequence to downregulate the translation of mRNA. Long non-coding RNAs (lncRNAs) which are transcripts 200 nucleotides in length could promote gene activation and inhibition by interacting with epigenetic regulators. lncRNAs are transcribed by Polymerase II enzyme, capped of 5' end, alternatively spliced and polyadenylated.

2. EPIGENETIC MECHANISMS IN HEART DEVELOPMENT

Heart being one of the first organs to develop during embryogenesis has a complex development process which involves coordinated cellular proliferation, migration, differentiation, programmed cell death and structural remodeling including looping and septation. Nucleosome remodeling, DNA methylation, and histone modification are processes controlled by enzymes that are dependent on the correct activation of a gene program which is necessary for the accurate growth of the mammalian heart during embryonic period and the terminal differentiation in the adult. Defects in the aforementioned processes result in deleterious phenotypes like septal defects, atrioventricular malformations, or developmental absence of right or the left heart and may end with mortality anytime during embryogenesis [10]. Epigenetic mechanisms have been implicated during the development of the heart in both directly by regulation of gene expression patterns as well as indirectly by modulating the expression of transcription factors.

Chromatin remodeling complexes catalyze the relocation of nucleosomes to modulate the accessibility of transcription factors and other regulatory proteins to DNA. There are multiple distinct families of chromatin-remodeling complexes [11]. For example, the SWItch/Sucrose Non-Fermentable (SWI/SNF) complex is an evolutionarily conserved multisubunit chromatin remodeling complex that are critical for differentiation and proliferation. SWI/SNF family exists in several subgroups and each subgroup contains one of two related ATPases, *Brahma-related gene-1* (BRG1) or *Brahma* (BRM), and BRG1-associated factors (BAFs) per complex [12]. BAF and PBAF (Polybromo-associated BAF), SWI/SNF members, are structurally related but functionally distinct. As shown by multiple studies, when a cell differentiates from a pluripotent stem cell to a multi-potent progenitor leading ultimately into a terminally differentiated state the configuration of SWI/SNF complexes are changed. Brg1 null mouse embryos die shortly after E11.5 day post-conception when cardiomyocyte expansion and maturation begins [13]. This fact proves the importance of Brg1 during cardiac development. Thinning of the compact myocardium and failure to form an inter-ventricular septum are the cardiac defects seen in these embryos. These defects are harmonious with a loss of cardiac factor Bmp10 expression and up-regulation of cell cycle inhibitor p57 (Kip2) thus portraying a decrease in cardiac myocyte proliferation [14].

The BAF180 subunit of the PBAF chromatin remodeling complex facilitates the ligand dependent transcription of nuclear receptor genes such as Retinoid X receptor-alpha (RXRa), Vitamin D Receptor (VDR), and peroxisome proliferator-activated receptors (PPARs) in vitro [15]. BAF180 knockout mice are prone to be a mortality at around the 15th post-conceptual day. They display severe hypoplastic ventricular development. Ventricular wall thinning with ventricular septal defect is observed histologically in the hearts of BAF180 knockout mice [16]. BAF180 is indispensable for coronary vessel formation. During the embryogenesis of the heart BAF180 is expressed sufficiently especially in the pro-epicardium and epicardium [16].

There is a relationship between cardiac-specific transcription factors and histone modifiers that constitutes a mechanism for target specificity. During the early stages of cardiac development a key transcription factor called Nkx2.5 regulates the development of myocardial precursors [17]. Precise regulation of cardiac gene expression is possible with multiple layers of interactions between Nkx2.5 and epigenetic factors such as histone demethylase/methyltransferases. Defects in either Nkx2.5 or epigenetic factors that interact with Nkx2.5

have the potential to end up with congenital heart disease. Modulation of the expression of *Jumonji*, *AT Rich Interactive Domain 2* (*Jarid2/Jmj*), and a component of a protein complex that contains histone demethylase and methyltransferases activities, in the second heart field by *Nkx2.5* itself might contribute to the epigenetic regulation [18]. *Nkx2.5* mutations have been linked with various septation and atrioventricular conduction defects in humans. Patients with congenital heart disease often showed decreased DNA binding and transcriptional activation by mutant *Nkx2.5* when compared with wild type. With loss of *Nkx2.5*, the expression of *Atrial natriuretic factor* (*ANF*), brain natriuretic peptide, myosin light chain 2 ventricular (*MLC2V*), Myocyte Enhancer Factor 2C (*MEF2C*), *Heart And Neural Crest Derivatives Expressed 1* (*HAND1*), *Msh Homeobox 2* (*Msx2*), and *iroquois homeobox 4* (*Irx4*) was significantly lost [19].

Congenital heart defects are among the most common of all medically significant birth defects. Several large population-based studies estimate the prevalence of congenital heart defects to range from 3 to 6 cases per 1000 live births [20]. Some syndromes, including Wolf–Hirschhorn syndrome, Holt–Oram syndrome, CHARGE syndrome, DiGeorge syndrome are related to congenital heart defects caused by the defects in epigenetic regulation. For example, CHARGE syndrome is defined by coloboma of the iris or retina, heart defects, atresia of the choanae, retardation of growth and/or development, genital, and ear abnormalities. Most of the children (71%) diagnosed with CHARGE have genetic mutations in the chromodomain helicase DNA-binding 7 (*CHD7*) gene. *CHD7* gene is a member of the chromo domain helicase DNA binding family of ATP-dependent chromatin modifiers [21]. *CHD7* is associated with all three forms of methylated histone H3 lysine 4 (*H3K4*), but most robustly with the mono-methylated (*H3K4me1*) and di-methylated (*H3K4me2*) sites as shown by analysis [19]. *CHD7* binding sites were found to be located further away from the transcriptional start sites, overlapping with DNase hypersensitivity sites. This reveals that *CHD7* may bind to and regulate putative enhancer regions or insulator elements for the deposition of epigenetic markers that define lineage specification [22].

2.1. DNA Base Modifications

Gametogenesis, hematopoiesis and stem cell differentiation, as well as various disease processes are several developmental processes in which DNA methylation patterns and dynamics have been described. The role of DNA methylation in regulation of heart development is under-studied. The role of DNA methylation in outflow tract septation through promoter regulation of the Van Gogh-like (*VANGL2*) gene has been suggested by recent scientific data [23]. *VANGL2* is essential for the polarization of cells at the outflow tract. The homozygous mutation of the gene in mice results in a phenotype resembling Tetralogy of Fallot (overriding aorta, double-outlet right ventricle and ventricular septal defects). *VANGL2* promoter methylation has been found to be elevated in patients with Tetralogy of Fallot when compared with healthy controls [24]. Genomic location within cells, cell types within the developing heart, as well as across various stages of development are factors which vary the role of DNA methylation in heart development.

Studies in embryonic stem cell (ESC) or animal models are the sources that provide our knowledge on DNA methylation. Inhibition of DNA methylation in ESCs by 5-azacytidine (5-azaC) has been shown to induce cardiomyocyte differentiation [25]. However, recent studies

on murine embryonic heart development have shown that heart development is associated with increases and decreases (greater increases than decreases) in DNA methylation, especially in cardiac-specific genes [26]. Studies with mice lacking key enzymes involved in the regulation of DNA methylation and demethylation were the first to suggest the gravity of DNA methylation in the development of the heart. The balance between DNA methylation and demethylation is imperative for proper mammalian development as portrayed by these results. The absence of DNMT1 led to global hypomethylation and early embryonic death as shown in these studies [27, 28]. DNMT3A-null mice survive until birth but die around 4 weeks of age, whereas DNMT3B-null mice die during gestation [29]. These findings are consistent with studies of postnatal cardiac development in rats, showing increases in DNA methylation in cardiomyocytes, as well as increased DNMT1, Methyl-CpG binding domain protein 1-3 (MBD1-3) and methyl-CpG-binding protein 2 (MeCP2), over the weeks and months following birth [30].

2.2. Histone Code

Epigenetic histone modifications have important roles in both normal and abnormal development as suggested by recent evidence. Factors that affect cardiac development are histone methylation and demethylation, acetylation and deacetylation status.

The status of histone methylation affects cardiac development. Being a histone methyltransferase, SET And MYND Domain Containing 1 (SMYD1) has been proposed to play a role in the development process of the heart. Mice lacking SMYD1 exhibit hypoplastic right ventricles and embryonic lethality [31]. In addition, Hand2 and Irx4 transcription factors, which are essential for normal cardiomyocyte development are found to be reduced in these mice [31, 32]. These changes suggest that SMYD1-mediated histone methylation is prerequisite for the expression of these essential cardiac transcription factors. Histone demethylase Jumonji family members have been proposed to have a role in septation. In the case of their deletion, ventricular septal defects and outflow tract defects are observed [33, 34]. Lysine (K)-specific demethylase 1A / Lysine-specific histone demethylase 1A (LSD-1/KDM1A) is another lysine demethylase that plays a role in the formation of ventricular septal defects [35].

The Creb-binding protein (Cbp) and p300 are two HATs and play critical roles in physiological and pathological growth of cardiac myocytes [36]. Cardiovascular defects and embryonic lethality are observed in p300 knockout mice, which die between days 9 and 11.5 of gestation and show reduced expression of muscle structural proteins such as β -MHC and α -actinin, as well as cardiac structural defects and reduced trabeculation [37, 38]. The potential connection between p300 regulatory complex and the actions of cardiac signals has led to the identification of transcription factors such as GATA binding protein 4 (Gata4), Mef2d, and myogenic differentiation (MyoD), as well as Mef2c involvement with transcriptional programs that result from signaling cues that control pathological gene expression in the heart [39].

Effects of histone deacetylation have been investigated in the development process of the heart. HDAC1 and 2 seem to have prominent roles in cardiac development. Double knockout mice show cardiac defects. Mice lacking HDAC1 and 2 are lost in the early periods of neonatal life. Their mortality is due to cardiac arrhythmias and dilated cardiomyopathy [40]. Being associated especially with cardiomyocyte metabolism and proliferation, HDAC3 has indeed

been thought to have a role in heart development. HDAC3's loss leads to impairment of glucose metabolism, thus provides an inclination towards an increase in lipid metabolism [41]. Overexpression of HDAC3 promotes proliferation of cardiomyocytes by the reduction of cell cycle inhibitors. As a result of these data it can be concluded that histone modifications lead to major alterations in heart development.

2.3. MiRNAs and lncRNAs

Loss and gain-of function studies demonstrated that miR1 and miR133 families are an essential miRNAs in the cardiac development [42]. In mice, mostly expressed miRNAs in the heart are miR1 (miR1-1, miR1-2, and miR206) and miR133 (miR133a-1, miR133a-2, miR133b) [43]. MiR133 targets cyclin D2 and serum response factor (SRF) and negatively controls cardiomyocyte proliferation [44]. In addition, miR208 and miR499 are highly expressed in the heart [45]. Also, it is found decrease levels of miR133 in the infarcted areas of the heart [46].

MiR1 promotes cardiac specification [47]. It has been shown that increased miR1 expression was associated with decreased ventricular cardiomyocyte proliferation [42]. It is suggested that mir208a regulates mediator complex subunit 13 (MED13) expression and controls systemic energy homeostasis [48]. MiR499 enhances myocyte differentiation [49]. In addition, miRNAs could control cardiovascular differentiation [50].

Recent studies suggested the importance of lncRNAs as regulator molecules of transcriptional regulation in cardiovascular development. Braveheart (Bvht), one of the lncRNAs, is expressed in the early stages of embryonic heart development [51]. Bvht interacts with the epigenetic silencing complex, polycomb silencing complex 2 (PRC2), and affect the expression of critical genes during early cardiac development [52, 51]. PRC2 contains trimethylates histone H3 at Lys 27 that promotes tissue-specific differentiation [53, 54]. PRC2 has an important function during early and late cardiac development and homeostasis [55].

Another lncRNA, Foxf1 adjacent non-coding developmental regulatory RNA (Fendrr), is exclusively expressed in mesoderm and plays a role in the development of mouse heart [43]. Fendrr modulates the chromatin signatures of genes which forms and differentiates the lateral mesoderm [52]. Fendrr may also control the activating of HE3K4me3 mark on promoters. Several studies suggested that Fendrr inactivation causes to defects in vascularization [55].

Discovery of Bvht and Fendrr functions support the role of lncRNAs in cardiac development.

3. Epigenetic Mechanisms in CVDs

Our current scientific knowledge cannot fully describe the complex pathophysiology of CVD yet. Epigenetics provides a different path to approach human disease. The dynamic nature and response to environmental cues of epigenetic processes constitute a plan for apprehending the constraints to CVD research which focused solely on the static DNA code.

3.1. DNA Base Modifications

Atherosclerosis is characterized by chronic inflammation of the arterial wall. When atherosclerosis affects the arteries of the heart, it's called CHD. CHD is the most common form of CVD and also called coronary artery disease. Differentially methylated CpGs association with the onset of atherosclerosis onset together with endothelial and smooth muscle functionality was shown in a DNA methylation map of human atherosclerosis. In the atherosclerotic lesions, a gain of DNA methylation was observed. This process strikes the opportunity to develop DNA demethylating agents for therapeutic aims. The global DNA methylation profile of peripheral blood leukocytes may produce a suitable biomarker for increased CHD risk [56].

Homocysteine (Hcy) is one of the known risk factors for atherosclerosis and CVD. Its action may be caused by an epigenetic mechanism involving methylation. Hcy is biochemically linked to the principal epigenetic tag found in the DNA. High levels of Hcy in circulation are a risk factor for CVD. Nonetheless, in recent clinical trials where folate and/or other vitamin B therapies were used to lower Hcy; cardiovascular event rates did not decrease, making Hcy's direct causative role in vascular disease controversial [57]. In a lot of *in vivo* studies it was suggested that Hcy levels may modulate global DNA methylation. For example, in healthy human subjects, increased levels of plasma Hcy were linked with both increased S-adenosylhomocysteine concentrations and DNA hypomethylation in lymphocytes [58]. Vascular complications associated with high levels of circulating Hcy was partially caused by DNA hypomethylation in several studies [59]. Increased levels of plasma Hcy was observed with decreased DNA methylation in CVD patients. This situation supports the role for hyperhomocysteinemia (HHcy) in the modification of epigenetic mechanisms. In a study done by Ingrosso and colleagues increased levels of Hcy together and reduced global lymphocyte DNA methylation pattern was reported [60]. After the reduction of the plasma Hcy levels with folate administration both global DNA methylation patterns and allelic gene expression were normalized. Data suggests that HHcy is linked with reduction in global levels of CpG methylation and gene-specific methylation of promoters [61, 62]. Changes in the expression of specific genes are seen with these alterations. The increased expression of the nuclear factor- κ B (NF- κ B) transcription factor, interacts with the IRE1 and c-Jun NH2-terminal kinase family of proteins [63]. This increased expression may cause inflammatory-mediated vascular damage [64]. With the finding of recent data it was suggested that that alterations in lipid metabolism may play a role in vascular pathology associated with HHcy [64, 65]. Many studies propose that epigenetics may play a role in these processes. In mice with Hhcy, it was suggested that changes in DNA methylation have might be the potential mechanism for altered *apoA-I* and *apoA-IV* gene expression [66, 67]. Hcy is significantly and inversely correlated with HDL-bound cholesterol and apoA-I in both human and murine models of Hhcy [68].

In vascular smooth muscle cell (VSMC) phenotypic modulation in human atherosclerosis, certain atheroprotective genes like *ER α* and *ER β* (*ESR1* and *ESR2*, respectively) which encode estrogen receptors (ERs) are hypermethylated [69]. ERs are found in the coronary arterial walls on both the smooth muscle cells (SMCs) and the endothelial cells (ECs). Their functions protect against atherosclerosis, especially in CHD. Deficiencies in *ER α* give way to accelerated atherosclerosis in humans [70]. Hypermethylation of *ESR1* was also seen in *in vitro* senescing ECs and SMCs, together with *ESR2* hypermethylation. With the light of these findings epigenetic changes in both *ESR1* and 2 can influence vascular aging and atherosclerosis.

Demethylation using 5-aza-2-deoxycytidine (DAC) could enhance the expression of silenced genes. These treatments increased the expression of ER α and ER β in normal SMCs and ECs. DAC and/or trichostatin A treatments showed low toxicity in these cells [71]. Silencing of ERs in women, with epigenetic changes, might explain the failure of estrogen therapy to exert a cardioprotective effect. The combined use of epigenetic therapy and hormone replacement therapy could be suitable for the prevention of CVDs [71, 72].

Zhu and colleagues portrayed that methylation of the monocarboxylate transporter gene suppresses its transcription leading to the passage of smooth muscle cells and the progression of atherosclerosis in cultured tissues of aorta and coronary arteries with varying degrees of atherosclerosis [73]. The risk of vascular damage may increase with the loss of the atheroprotective factors expressed by these genes.

In patients with atherosclerosis, global DNA methylation decreases in the peripheral blood cells [74]. The era of DNA methylation in atherosclerosis was uncovered by two different groups [75, 76]. They portrayed coexistence of hypomethylation with atherosclerotic lesions in mice and rabbits. It was shown in other studies that hypomethylation could be detected at the early stages of atherosclerosis, before the appearance of the anatomical manifestations of the disease [77]. Baccarelli and colleagues revealed an association between hypomethylation of long interspersed nucleotide elements-1 (LINE-1) and higher incidence of ischemic heart disease [56]. Friso and colleagues showed that hypomethylation of the promoter of coagulation factor VII was linked with coronary artery disease in patients, who are angiographically proven to have coronary lesions [78].

Heart failure is a condition caused by the heart failing to pump enough blood around the body at the right pressure. The etiology of HF is quite complex depending on genetic predisposition and multiple environmental factors. Development of HF depends on several molecular and cellular mechanisms. These include reprogramming of the expression of certain critical cardiac genes. Downregulation of the alpha-myosin heavy chain (alpha-MHC) gene and sarcoplasmic reticulum Ca⁺ ATPase genes and reactivation of specific fetal cardiac genes such as atrial natriuretic factor and brain natriuretic peptide are examples of these cardiac gene alterations [79].

Changes in patterns of methylation and extent of regulatory regions of genes is known to modify their expression which correlates with status of HF. Without respect to the etiology of HF there are three angiogenesis-related genes that are found to have differential methylation. Hypermethylation of the 5'-regulatory region of platelet endothelial cell adhesion molecule-1 and hypomethylation of the angiomin like protein-2 (AMOTL2) are noted in HF [80]. These are closely linked with reduced expression of these genes. Hypermethylation within the Rho-GTPase activating protein-24 gene (ARHGAP24) in failing hearts is associated with elevated expression of this gene [80]. Movassagh and colleagues showed that three angiogenesis-related genes underwent differential methylation, irrespective of the etiology in patients with HF [80]. *AMOTL2* gene was hypomethylated whereas the 5' promoter region in the platelet/endothelial cell adhesion molecule gene and the gene body of *ARHGAP24* were hypermethylated [80]. The modified epigenomics of the three genes in endstage HF may reflect common epigenetic pathways in heart remodeling and vasculature. Dilated cardiomyopathy is seen in 33% of cases of HF. Nguyen and colleagues in a mouse model proved that cardiac specific knockout of telomeric silencing-1-like (DOT1L), the gene encoding for the HKMT Dot1L which catalyzes H3K79 methylation in mammals that gave way to the appearance of a phenotype similar to that seen in dilated cardiomyopathy [81].

Hypertension is a multifactorial disease whose pathogenesis is underlined by several mechanisms due to the complex interplay of genetic and environmental factors. Epigenetic mechanisms play a role in the pathogenesis of hypertension. Global 5mC levels of peripheral blood cells in patients with essential hypertension were found to be lower than healthy controls. The levels of 5mC correlates with the the stage of hypertension in these patients [82]. Valinluck et al. reported that 5hmC at CpG sites was discovered to suppress the binding of MeCP2 [83]. MeCP2 is a transcriptional repressor which probably has a potential role of 5hmC in gene expression regulation [83]. 5hmC may have a role in mediation of fetal heart and lung growth [84].

The role of gene-specific DNA methylation in the pathogenesis of hypertension has been recently proposed. 5hmC has a role in determining tissue-specific gene expression and regulating the expression of genes involved in cellular differentiation and pluripotency [84, 85]. In patients with essential hypertension, promoter methylation of 11 β HSD2, the gene encoding 11 β -hydroxysteroid dehydrogenase 2 (11 β HSD2), has been shown to be increased in the peripheral blood mononuclear cells [82]. 11 β HSD2 breaks down cortisol to its biologically active form, cortisone. Reduction in the activity of 11 β HSD2 promotes cortisol-mediated activation of mineralocorticoid receptors thus end up in increased blood pressure [82]. An increase in the risk of development of adult type hypertension and an increase in promoter methylation at hydroxysteroid (11-beta) dehydrogenase 2 (HSD11B2) site were observed in an intrauterine growth restriction (IUGR) rat model of hypertension [86]. Methylation levels at HSD11B2 promoter sites were significantly higher in IUGR newborns when compared with controls. This was related to lower HSD11B2 expression [87]. The pattern of methylation at different CpG sites were in conjunction with birth weight and ponderal index which are measures of fetal growth [87]. Methylation of the promoter at HSD11B2 site may associated with development of IUGR and the possible risk of future development of hypertension [87]. Another human study suggests that promoter methylation of HSD11B2 gene is closely linked to hypertension [88]. Methylation at HSD11B2 promoter in DNA of peripheral blood mononuclear cell (PBMCs) of hypertensive patients is inversely related to the function of the enzyme [88].

Somatic angiotensin-converting enzyme (sACE) is another major mediator of blood pressure regulation which is influenced by DNA methylation in human cell lines [89]. With the combination of knowledge from these it can be suggested that aberrant DNA methylation could lead to the formation of essential hypertension in a gene-specific manner. Overall reduction in global methylation is indicative of the progression of disease.

The role of membrane transporter genes for the known role of alterations in ion flux mechanisms in the pathogenesis of hypertension have been also evaluated. Promoter methylation of the Na⁺/K⁺/2Cl⁻ cotransporter 1 (NKCC1) was studied by Lee et al. [90]. NKCC1 is a gene that encodes a solute carrier which is responsible for the transportation of sodium, potassium, and chloride through the cellular membrane. In spontaneously hypertensive rats, the methylation status of NKCC1 promoter were measured in the aorta and the heart [90]. In the study it was concluded that in a spontaneously hypertensive rodent model NKCC1 expression is upregulated by a mechanism induced by gene promoter hypomethylation [90].

Cardiomyopathies are defined as diseases of the myocardium associated with cardiac dysfunction. There are two types of cardiomyopathy: primary (idiopathic) or secondary to ischemia or myocardial infarction. They can also be defined on the type of remodeling. Ventricular dilation and hypertrophy take place as the patient develops HF.

DNA methylation patterns in the hearts of patients undergoing cardiac transplantation for primary or secondary cardiomyopathy were investigated in two current studies [91, 92]. Genomic profiling of DNA methylation in end-stage HF patients who have primary or secondary cardiomyopathy showed significant hypomethylation at the promoter regions and hypermethylation at the gene body regions when compared with healthy controls with normal hearts. There was no statistically significant difference in intergenic regions, including enhancer regions [92]. Haas et al. studied patients with primary cardiomyopathy and found that there was statistically significant difference in differential methylation in pathways related to cardiac disease, as well as differential methylation of several key genes when compared with healthy controls with normal hearts [91].

3.2. Histone Code

NOS3 is the well-characterized endothelial gene that has cardiovascular implications and it is controlled by histone modification. eNOS is a protein which is coded by the NOS3 gene. It catalyzes the formation of NO from L-arginine in blood vessels [93]. NO is a factor responsible for vasodilation. It has a major part in the regulation of vascular tone and protection against atherosclerosis [93]. The NOS3 gene is transcriptionally active in ECs and it is transcriptionally suppressed in VSMCs under normal conditions [94]. Acetyl H3K9, acetyl H4K12, and methyl H3K4 at the NOS3 proximal promoter site in ECs are activating histone modifications. When they are present they allow the recruitment of RNA polymerase II (RNAPII) [94]. In VSMCs, eNOS expression is suppressed by the absence of activating histone modifications at the NOS3 proximal promoter. It is further suppressed by the presence of cytosine methylation and MeCP2 recruitment [94]. The expression of eNOS is controlled by environmental stimuli. If short term hypoxia is experienced by the ECs, a reduction in the expression of eNOS is observed [95]. Significant reduction in NOS3 transcription observed in the ECs when faced with hypoxia is considered to happen via histone eviction, including processes that are in relation with transcriptional activation (acetyl H3K9, methyl H3K4, acetyl H4K12), at the NOS3 proximal promoter site [95]. H3 and H4 activating acetylation marks are activated by laminar shear stress. This is partially accomplished by the p300 HAT complex, at a shear stress reporter element in the human eNOS promoter [96]. The fusion of the activating acetylation marks via laminar shear stress provides for the chromatin at the eNOS shear stress reporter element site to stay in an open, transcriptionally-accessible state, permitting eNOS expression.

The activity of HDAC seems to have a major part in the prediction of the degree of myocardial ischemia and reperfusion damage especially after an MI [97]. There is proof that myogenesis and angiogenesis are stimulated in embryonic stem cell cultures with the inhibition of HDACs [98]. In vivo studies in mouse portrayed that by prevention of myocardial remodeling and a reduction in myocardial and serum tumour necrosis factor alpha, inhibition of HDAC improved functional myocardial recovery after MI [98]. Increases in the formation of myocytes and microvessels in the heart were seen after the inhibition of HDAC. After MI there is loss of myocardial performance due to stimulation of angiogenesis [98]. With the light of these findings it can be said that HDAC inhibition can make a reduction in the loss in myocardial performance by inhibiting angiogenesis [97]. The administration of the pharmacologic HDAC inhibitor TSA to atherosclerosis-prone Ldlr (-/-) mice exacerbated

neointimal lesions [99]. With better understanding of epigenetic pathways with the help of animal models of atherosclerosis there is more to be discovered.

Curcumin (diferuloylmethane) is a polyphenol present in a curry spice. It is p300 HAT inhibitor which has a wide variety of molecular targets including transcription factors, growth factors and their receptors, cytokines, enzymes, and genes regulating cell proliferation and apoptosis. Curcumin has cardioprotective function [100]. In studies done in patients with atherosclerosis and healthy controls, its administration decreases LDL levels, increases high-density lipoprotein (HDL) levels [101, 102]. Moreover, both in a rat model of HF and primary cultured rat cardiac myocytes and fibroblasts, curcumin inhibits p300 HAT activity thus preventing ventricular hypertrophy, and preserving systolic function in rat model of HF and primary cultured rat cardiac myocytes, fibroblasts [103]. In the rat cardiomyocytes, curcumin is thought to act by inhibition of histone acetylation and hypertrophy-responsive transcription factors (e.g., GATA4), and by disruption of p300/GATA4 complex [104].

In the experimental animal CH models, CH was found to be closely associated with histone acetylation. HATs and HDACs are both playing major roles in this process. It has been shown that hypertrophic growth of cardiomyocytes could be induced by the depending on their HAT activity both overexpression of transcriptional co-activators CREB binding protein (CRB) or p300 itself may induce hypertrophy in cardiomyocytes [105]. Phenylephrine-induced hypertrophic cell growth may be suppressed by the suppression of these co-activators. Catalytic activity of p300 or overexpression of CBP may give rise to hypertrophy. On the contrary mutant forms of these without HAT activity do not end up with the same effects [105]. However, the activity of HDACs' was found to be involve both prohypertrophic and antihypertrophic pathways leading to controversial data. Class IIa type HDACs were discovered to inhibit CH [106]. However, in other animal in vivo studies HDAC inhibitors were found to have a protective role against hypertrophy. In the study by Liu and colleagues done on cardiac hypertrophy model in transgenic mice it was portrayed that injection of a specific HDAC inhibitor reverses atrial fibrosis and diminishes atrial fibrillation vulnerability following an electrical stimulation [107]. Deletion of both HDAC-1 and HDAC-2 from the myocardium lead to early rodent mortality from fetal arrhythmia in other experimental models [40]. Also, Chen and colleagues revealed that inhibition of HDAC suppresses myocardial remodeling [108].

New data uncovers the relationship between histone acetylation and vascular inflammation. Interleukin (IL)-1 β , IL-6 and tumor necrosis factor (TNF)- α are some of the proinflammatory cytokine that are decreased by HDAC inhibitors as shown by multiple in vivo studies [109, 110]. The function of histone modifications in VSMC phenotypic modulation and proliferation in response to these cytokines have been studied in multiple other studies [111].

In a histone epigenetic modification study done by Wierda et al. it was shown that hypomethylation was linked with pathophysiological status [112]. Immunohistological examination of the samples taken from perirenal aortic tissues from clinical organ transplant cases, where morphological evidence of progression of atherosclerosis was more evident, showed that fewer nuclei exhibited trimethylation status at lysine 27 of histone H3 (H3K27Me3) [112].

Histone modifications play their role in HF. Kaneda and colleagues focused on genome-wide histone methylation of heart tissues [113]. They reported that tri-methylated histone H3H4 and H3K9 were altered in HF.

In animal models, especially H3K9 and H3K4 type, histone methylations are related with CH. Hypermethylation associated to hydroxymethylation of epidermal growth factor receptor

(EGFR) gene was found to be linked with aortic valve calcification and subsequent ventricular hypertrophy in another study that utilized experimental mice model [114].

Many histone modifications are discovered to have a role in the pathophysiology of hypertension. Following pressure overload in the heart, in more than half of the differentially expressed genes methylation or acetylation alterations are seen [115]. Hypermethylation of H3 by disruptor of DOT1-Like Histone H3K79 Methyltransferase (DOT1L), a methyltransferase, enhances the expression of hypertension-promoting telomeric genes [116]. DOT1L also has a role as an antihypertensive. The antihypertensive role is played by the suppression of amiloride-sensitive renal epithelial sodium channel (ENaC) expression [117]. DOT1L is suppressed by aldosterone. As a result of this ENaC expression increases leading to an increase in blood pressure. In several animal models it was found that lack of LSD1 caused hypermethylation of H3 which in turn lead to increased inclination to hypertension [118]. When mice fed a high-salt diet, LSD1 deficiency was closely linked with arterial hypertension. LSD1 induces demethylation of H3K4 or H3K9 changing gene transcription [118]. In the high-salt diet group, LSD1 deficiency lead to hypertension, enhanced vascular contraction, and reduced relaxation via nitric oxide–cyclic guanosine monophosphate pathway [118]. This finding portrays that LSD1-mediated histone demethylation has a role in modifying NOS/guanylate cyclase gene expression and blood pressure.

Status of histone acetylation is involved in the control of blood pressure. Epigenetic modulation has a function in the beta2 adrenergic receptor–GR–WNK4 pathway. Data from murine studies suggest that this pathway is linked with the activation of HDAC8 [119]. HDAC8 reduces the binding of the acetylated histones 3 and 4 with the promoter of the WNK4 gene. This reduces the transcriptional activity of WNK4 through the recruitment of glucocorticoid receptors to a negative glucocorticoid response element [120]. WNK4 is a member of serine/threonine kinase family which down regulates expression of sodium chloride transporters and epithelial sodium channels [121].

Hyperglycemia with prolonged exposure induces specific chromatin alterations and transcriptional responses. These illustrate the role of epigenetic events controlling signaling pathways relevant to diabetic CVD [122]. Genome-wide analysis of human vascular cells demonstrates that histone modifications and DNA methylation take place at the same time under hyperglycemic conditions allowing for prediction of gene expression [123]. In the study done by Mutshtov and colleagues it was proved that insulin gene in human islet-derived precursor cells showed increased levels of histone modifications (H4 hyperacetylation and dimethylation of H3 lysine 4) which is indicative that a gene is active [124].

Alterations in epigenomics can happen in the inflammatory pathways with hyperglycemia. In the study performed by Villeneuve and colleagues, it was discovered that there was a rise in the expression of inflammatory genes in vascular cells cultured in high glucose. On the other hand, H3K9me3 expression was reduced at its promoter [125]. H3K9me3 is a histone H3 which prevents against the biochemical state of diabetic inflammation. El-Osta and colleagues portrayed that the slightest transient exposure to high levels of glucose induced sustained epigenomic alterations in the p65 subunit promoter of the NF- κ B [126]. This change altered the epigenomics of cultured aortic endothelial cells. This could be in part the reason of the irreversibility of cardiovascular complications of long-standing uncontrolled diabetes which is usually the case in the routine clinical setting.

3.3. MiRNAs and lncRNAs

Some of the miRNA and lncRNA molecules are under study to define the association between epigenetic control and the development of CVDs. We focus on the role of several miRNAs and lncRNAs in many CVDs.

Several miRNAs are known to be associated with atherosclerosis. It has been reported that atherosclerosis patients had reduced levels of miR-126, miR-17, miR92a (in endothelial cells), miR-145 (in smooth muscle cells), and miR-155 (in inflammatory response-associated cells) in plasma and serum [127]. Conversely, miR-133 and miR-92-a (in cardiac muscle) were significantly increased in plasma of atherosclerosis patients [127]. In addition to these findings, it is compared many miRNA levels in atherosclerosis patients with stable and unstable angina. And this research group showed that unstable angina patients had significantly increased levels of miR-134, miR-370, and miR-198 vs stable angina patients [128]. The other research group compared the platelet miRNA levels between control and patients with atherosclerosis. They revealed significantly increased miR-340 and miR-624 levels in atherosclerosis patients [129]. It has been recently shown that miR146a-miR146b are implicated in the pathogenesis of atherosclerosis [130].

Recently, it has been shown that increased expression of an antisense lncRNA (ANRIL, antisense non-coding RNA in the *INK4* locus) is associated with the severity of atherosclerosis [130]. Also, another study found that SNP rs10757278 in the *INK4* locus is related with loss of ANRIL expression and increased risk of atherosclerosis [131]. Cunningham and colleagues showed an association between SNP rs1333045 and susceptibility of atherosclerosis [132].

Several studies have been performed to define the association of miRNAs with MI. In a human study, Bostjancic and colleagues found an increased levels of miR-208 in MI patients compared with healthy controls [46]. MiR-1 is one of the most studied miRNA. It has been shown that plasma miR-1 levels were significantly increased in MI patients vs healthy controls [133, 134]. Furthermore, there was a significantly positive correlation between miR-1 expression and infarct size in rat tissues [135].

D'Alessandra and colleagues analyzed the pattern of miRNAs plasma in patients with acute MI and healthy controls. Onset of MI symptoms showed significantly increased miR-1, miR-133a/b, and miR-499-5p in plasma [136]. In consistent with these results, another research group revealed a markedly increased of plasma miR-499 in MI patients [137].

Little is known about the association between lncRNAs and MI. Myocardial infarction-associated lncRNA transcript (MIAT) is a one of the risk factor for MI. Vausort and colleagues found higher MIAT levels in MI patients than healthy controls [138]. The same research group also showed an increased ANRIL expression in MI patients [138].

Many studies have determined a significant role of miRNAs in the pathogenesis of HF. The levels of several miRNAs showed alterations in animal models of HF and in patients with human cardiac [139]. While transgenic miR-195 mice had dilated cardiomyopathy, increased expression of miR-23a, miR-23b, miR-24, miR-195, and miR-214 induced hypertrophy in human cardiomyocytes [139]. In addition, overexpression of miR-133 decreased protein synthesis and inhibited hypertrophic growth of mouse cardiac myocytes [140].

Furthermore, Fukushima and colleagues has studied plasma miRNAs profiling in HF patients. They found that patients with HF had reduced miR-126 plasma concentration compared with healthy controls [141]. Also, the profiling of miRNAs has been analyzed by

Corsten and colleagues, only miR-499 levels were significantly increased in HF patients compared to controls [142].

Recently, it has been defined markedly expression changes of lncRNAs in various mice and human models of HF. It was found that Pdk1 knockout mouse models had severe HF [143]. Also, one report revealed elevated levels of long intergenic noncoding RNA predicting cardiac remodeling (LIPCAR) in patients with HF [55]. In addition, many research studies suggested that it can be an association of two lncRNAs, Fendrr and Bvht, in HF [52, 51].

MiRNAs were characterized as important regulatory elements in differentiation and maintenance of nervous system [144]. In rat studies, miR-290, miR-292-5p, and miR-497 were upregulated in blood and brain, on the other hand miR-210, miR-215, miR-324-3P, miR-422b, miR-451, and miR-154 were found to be increased only in brain [145].

Another study demonstrated an increased expression of miR-10a, miR-182, miR-200b, and miR-298 in animal models with induced stroke [146]. In converse, the same research group found that miR-155, miR-362-3p, miR-223, and miR-210 were significantly reduced expression in ischemic brain [146]. MiRNA expression has been also investigated in a human study. It has been shown overexpression of five miRNAs in symptomatic, stroke-related, and atherosclerotic plaques [147].

It is considered that there is an association of ANRIL with stroke. ANRIL may increase the risk of stroke via regulation of caspase recruitment domain 8 (CARD8). ANRIL regulates the expression of its downstream gene CARD8 [148].

In conclusion, definition of the miRNA and lncRNA profiles could have an important impact on understanding the pathogenesis of CVDs. Identification of the biological functions of miRNAs and lncRNAs in the cardiovascular system will be essential for CVD prevention, diagnosis, and therapy. Also, these molecules may have the potential to be used as prognostic biomarkers.

4. CARDIOVASCULAR RISK FACTORS AND EPIGENETICS

The majority of CVDs is caused by risk factors that can be controlled, treated or modified, such as diet and nutrition, tobacco use, obesity, lack of physical activity, high blood pressure, cholesterol and diabetes. However, there are also some major CVD risk factors (e.g., age, gender, family history) that cannot be controlled. When those risk factors are altered there could be a modification in epigenetics leading to a decline in the incidence of CVD.

Current evidence shows that epigenetic mechanisms can regulate nutritional effects. They can be the reason for the development of common complex or chronic diseases [149]. Nutritional factors are of major importance in CVD disease modification and prevention. Hypertension, atherosclerosis, many metabolic disorders, obesity, and weight-loss outcomes are affected by alterations in the epigenetic patterns. Histone modifications, DNA methylation, non-coding ribonucleic acid (ncRNA) expression, and chromatin remodeling resulting in a dynamic regulation of gene expression leading to control of the cellular phenotype are among the many different factors that show complex interaction with food components [150]. Changes in epigenetics seem to be more significantly linked with gene-nutrition and gene-environment interactions. The changes in lipid metabolism, inflammation, and other metabolic imbalances which resulted in CVD disease and obesity.

Obesity is often seen together with the metabolic syndrome. They both have major function in the establishment of CVD disease. Epigenetics have effects on both of them concerning the occurrence or prevention of CVD disease. In a study performed in pregnant mice, a high fat diet during pregnancy was found to be linked with epigenetic changes in the expression of adipocytokine genes [151]. Higher blood pressure, worse glucose tolerance, higher triglyceride levels, higher leptin levels and significantly lower adiponectin expression in white adipose tissue were seen in the offspring of the previously mentioned mice. The aforementioned relevance was with lower acetylation and higher methylation levels of histone H3 at lysine 9 of the adipose-tissue promoter of adiponectin [151].

Gene expression can be changed by epigenetic mechanisms imposed by nutritional factors. Recent data suggests that dietary lipids and their derivatives are dynamic modulators of pro- or anti-inflammatory gene expression pathways via nuclear receptors. These nuclear receptors take part in the regulation of various biological functions. Lipid metabolism, inflammatory mediator production, and vascular homeostasis are some examples of these biological functions. Selected dietary components may induce an atherosclerotic cellular phenotype. This could be partially done by producing epigenetic marks that shift differential gene activation and repression [74]. The PPAR receptor family is induced by small lipophilic ligands. These ligands are transcription factors involved in the regulation of genes in the cellular processes such as inflammation, beta-oxidation, and glucose homeostasis. They may be thought to be important targets for pharmacologic intervention in chronic diseases [74]. PPARs are major parts of a transcriptional network that imposes epigenetic marks. PPARs are also considered to be appropriate transcriptional response elements to specific ligands and molecules as factors that cross-talk with PPAR signaling. Fatty acids, intracellular inflammatory mediators, polyphenols, and multiple dietary factors that control the transcription of genes enrolled in the metabolic processes linked with inflammation and fatty acid metabolism are members of these factors.

Nutritional epigenetics may clear the way to understand the pathways of how nutrition can influence health with its effects on the genome. It is known that with administration of folate, homocysteine levels will be lowered. Nonetheless no reduction in the risk of CVD disease risk could be established. Some authors claim that a combination of vitamin B, folic acid, vitamin B6 and vitamin 12 could have harmful effects [152]. Especially during crucial times like fetal and postnatal development, nutritional effects on epigenetic programming could cause major effects to CVD disease [153]. An important therapeutic concept is that nutrients and medication could reciprocate epigenetic patterns. During special development milestones, epigenetic programming, or reprogramming could be effective mechanisms which may result in improvement in the health status of the patient. This could be achieved by dietary regulation [154].

Among the epigenetic modifications, DNA methylation is the most comprehensively investigated. Nutrition and other environmental stimuli can affect methylation. S-adenosylmethionine (SAM) is the prime methyl donor for DNA methylation. With the availability of specific dietary micronutrients such as folate, choline, betaine (trimethylglycine), and various B vitamins, this metabolism can be catalyzed by several enzymes. The relationship between nutrition and DNA methylation is endorsed by findings from animal studies. Epidemiological evidence from human studies is quite limited.

Folate affects the formation of SAM. SAM is a methyl donor for methylation of cytosines in DNA [155]. This kind of methylation is closely linked with gene silencing. Another part in

gene silencing is played by the covalent attachment of biotin to histones. This reaction is also involved in any cellular response to DNA damage. Tryptophan and niacin are converted to nicotinamide adenine dinucleotide (NAD). NAD is a substrate for polyADP-ribosylation (PAR) of histones and other DNA-binding proteins. PAR is involved in DNA repair and apoptosis. Epigenetic changes seem to be a mechanism to mediate the effects of environmental exposures in the early periods of life and gene-environment interactions on the development of adult type disease [156]. Maternal dietary consumption of fat, folate, protein, and the amount of total energy intake may change the epigenetic regulation of specific genes in the offspring. This could end up in functional changes in the tissues [157].

Raising the amount of vitamin D consumption does not seem to have major disadvantages. Current evidence shows that vitamin D could have important effects on epigenetics during the intrauterine period leading to reduction in chronic disease later in life. Vitamin D also has many potential benefits to wellbeing including CHD [158].

Flavonoids are potent inhibitors of DNA methyltransferases *in vitro*. They have the power to reverse hypermethylation and reactivate DNA repair genes. Folate is found in high concentration in green leafy vegetables. It mediates DNA methylation by its generation of SAM. People who have diets with low levels of folate or who have low levels of folate in their blood, have a significantly increased risk of developing CHD disease [159]. Nonetheless there is controversy about the possible lack of value, or even harm, from direct supplementation with folate combined with vitamins B6 and B12 [152, 160]. Folate is important in preventing certain birth defects. Supplementation of folate with myo-inositol in the early periods of pregnancy to a potential mother could alter the epigenetics aiding to prevent environmentally induced birth defects which are closely linked with congenital heart disease [161].

Epigenetic modifications that are affected by the intrauterine environment are investigated with the current animal studies. In a study, offspring of low protein fed pregnant mothers was found to have hypomethylated angiotensin type 1b receptor (AT1bR) gene promoters in addition to increased adrenal expression of AT1bR [162]. From this finding it can be inferred that specific hypomethylation could have a role in the regulation of elevated blood pressure. Overexpression of the hepatic glucocorticoid (GR) and PPAR α receptors in offspring were observed in the other studies that used a model of low protein diet receiving pregnant rats [163, 164]. A lot of different metabolic pathways could be affected by the key transcription factors GR and PPAR α receptors. They have been considered to have a role in the pathogenesis of several disease conditions like obesity, diabetes, and atherosclerosis [165, 166].

Risk of adult CHD disease, osteoporosis, and type 2 DM are increased in people who were small for gestational age at birth [167]. They also have poor growth rates in infancy. The increased risk more apparent when the early growth is restricted and it is followed by increased childhood weight gain [167]. The previously mentioned aspects are linked with epigenetic processes altering the phenotype of the offspring, reflecting the developmental responses of the fetus and/or infant based on environment.

Barker and colleagues hypothesized that environmental factors in crucial periods of early life (during fetal development, for instance) can influence risks for cardiovascular and metabolic diseases later in life [168]. This concept is supported by a number of studies that have associated low birth weight in human populations with increased risk of cardiovascular disease. For example, individuals prenatally exposed to famine during the Dutch Hunger Winter (1944–45) experienced higher prevalence of obesity and coronary heart disease as adults, when compared to adults born before or conceived after that period [169]. In Barker's

seminal work, it was found that low birth-weight babies who survived infancy had an increased risk of coronary heart disease later in life, and that increasing birth weight was associated with a graded decrease in risk [170].

In experimental animal models during the early stages of post-natal life exposure to different behavioral patterns was discovered to affect epigenetic modifications [171]. It could be hypothesized from this finding that the lifelong alterations are at the least partially affected by the epigenetic changes in the gene expression during the early periods of life [172]. When applied to the human population, social and environmental stresses during development that change epigenetic processes could be the reason of adult race-based US health differences seen in hypertension, diabetes, stroke, and coronary heart disease [173].

Wheatley et al. studied the hypothesis of modulation of adipose gene expression with the reversal of obese status by restriction of calories and exercise in 48 female mice [174]. 209 genes were found to be responsive to both calorie restriction and exercise in the gene expression microarray analysis of visceral white adipose tissue. 496 genes were affected by calorie restriction alone while just 20 genes were altered by exercise. 17 genes are related to carbohydrate metabolism and glucose transport from the genes which were responsive to calorie restriction. Glucose transporter 4 was among the genes affected by calorie restriction. Calorie restriction significantly increased acetylation of histone 4. This finding was in parallel with differential changes in adipose transcription with calorie restriction [174].

Long-term repetitive strenuous exercise is considered by many as having a positive effect on health, a reduction in aging, and leading to decreased incidence of disease. Modification of epigenetics can be achieved by physical exercise. Prevention from CVD disease by exercise can be explained by the exercise's power to modify epigenetics [175]. Possible benefits on health are caused by adaptations in skeletal muscle adaptations. These adaptations happen partly due to alterations in gene expression in the skeletal muscle. Chromatin remodeling by epigenetic histone modification seems to be the key regulatory mechanism modifying gene expression. Class IIa HDACs enzymes are closely linked with the adaptation in exercise. These enzymes inhibit histone acetylation. In their study McGee et al. portrayed that global histone 3 acetylation was increased at lysine 36, a site that was related with transcriptional elongation. They used cycling for 60 minutes as the method of exercise in their study [176]. They also discovered that that HDAC₄ and HDAC₅ were exported from the nucleus during exercise. The suppressive role of HDAC₄ and HDAC₅ was expelled.

In spite of the data that supports the positive influence of physical exercise on epigenetic mechanisms and an improvement in health, there is not a clear connection between exercise and epigenetics. Excessive and persistent physical exercise could in fact may have a negative influence on health. Gene expression may be affected by modified epigenetics that were changed by the body's physical adaptation to environmental conditions [175].

The functional genome in cardiac and peripheral vascular beds can be altered by exercise or physical activity. Reactive oxygen species (ROS) are formed during exercise but it also enhances anti-oxidative capacity. A deviation in the balance of cellular oxidative stress ensues. ROS have important regulatory function in muscle contraction, antioxidant protection, and repair of oxidative damage. DNA methylation and histone modification could have role in exercise-related ROS production thus leading to heritable conditions which are overseen by epigenetics. Many signal cascades controlling physiological and pathophysiological cardiac and peripheral vascular adaptations are modified [177]. The result is the modification in the

molecular composition of the extracellular matrix. As a result several signaling cascades are changed.

There are many epigenetic signatures of environmental exposure pertaining to CVD as discovered from different studies (population cohorts for global and gene specific alterations). Oxidative stress, aging, and atherosclerosis are CVD disease outcome measures [178]. Exposure to traffic-related air pollution is closely linked with an increase in hospitalization rates and mortality from the perspective of CVD disease outcome measures. Metals affect health in many perspectives [179]. Under the light of new data, epigenetics could be a crucial pathway where metals produce their effects on health. Metallomics studies concerning environmental toxins are using epigenetics as a brand new major area to make their investigations. DNA methylation, modification of histone proteins, and RNA interference are three factors which are involved in CVD disease and other inherited conditions that are being studied by epigenetics [179]. Tobacco is a well-known CVD disease risk factor. It exerts its effects through epigenetics [180]. DNA methylation, histone modification, and microRNA alterations are environmental epigenetic mechanisms produced by tobacco. Tobacco consumption by the mother has been linked with changes in methylation of placental cytochrome P450A1 (CYP1A1) gene restriction [181]. This change leads to fetal growth restriction. Recently there has been a new finding between the prognosis for patients with stable CVD and smoking-related methylation patterns in the Coagulation factor II (thrombin) receptor-like 3 (F2RL3) gene [182].

Recent evidences have also shown the role of modulating or modifying miRNAs in established several risk factors for CVDs. Dyslipidemia is a common increased risk factor for developing of CVDs. Decreased levels of atherogenic lipoproteins are related with reduced CVD risk [183].

Numerous studies are performed for analyzing the biological functions of miRNAs on lipid metabolism. MiR122 that is an emerging miR in animal model hepatocytes targets many genes required in lipid metabolism [184]. Two studies demonstrated that miR122 inhibition reduced the levels of total serum cholesterol by increasing the fatty acid oxidation and hepatic lipid synthesis [185, 186]. Furthermore, it has been shown that miR122 reduced triglycerides and decreased the synthesis of the LDL receptor [187]. Rayner and colleagues found that another miR, miR33, regulates the cholesterol homeostasis by modulating either HDL biogenesis in the liver or cellular cholesterol efflux [188]. In African green monkeys, suppression of miR33 reduced serum triglycerides and increased HDL [188]. A genome-wide association study defined that presence of rare rs13702 C allele within the miR410 leads to lower triglycerides and higher HDL [189].

Diabetes and obesity which are another emerging risk factors for CVDs modified by miRNAs. It has been found an increased miR103 and miR107 in obese and diabetic mice liver [190, 191]. The treatment with Anti-miR103/miR107 extends glucose homeostasis and suppresses the size of adipocytes and total amount of visceral fat in these mice [191].

One research group demonstrated the association between antisense inhibition of miR208 and markedly repression of weight gain in mice which were bleeding with high-fat diet [192].

Tobacco smoke has lots of different chemical compounds that are CVD disease-causing compounds. Nicotine is one of the compound of cigarette smoke. It has been demonstrated that miR133 and miR590 progressed the remodeling of atrial in the present of nicotine treatment by modifying the TGF- β 1 and TGF- β receptor II [193].

In addition, miR-197, miR-23a, and miR-509-5p were shown being correlated with body mass index, the risk factor for CVDs, in human study [194].

5. EPIGENETICS-BASED THERAPEUTIC STRATEGIES IN CVDs

Pharmacological therapy centered on the epigenome is a novel therapeutic concept. Pharmacoepigenomics uses epigenetic modification by medications as its basis of approach [195]. Pharmacoepigenomics might be able to more personally tailored treatment options. These kind of pharmaceutical agents are called epi-drugs. DNA methyltransferases, HDACs, HATs, histone methyltransferases, and histone demethylases are type of epi-drugs. Pharmacoepigenomics' major use was thought to be pharmacotherapy related to cancer [196]. However, currently new evidence shows that personally tailored oral antidiabetic treatment modalities could be more beneficial than standard treatments. In the future, pharmacoepigenomics could alter different individual response to oral antidiabetic treatment. Dysfunction of smooth muscle cells in diabetes could be the reason of increased incidence of macrovascular complications. Epigenetic modification of smooth muscle cell function may be the advantage of this treatment option as CHD risk in diabetic patients. Because, this treatment strategy does not require the tight glucose control in these patients [197].

CVD has a complex pathophysiological process and pathogenic pathways of CVDs remain unclear. Genetic approaches including epigenetics and personally tailored medical treatment established a novel approach in the treatment of CVDs. Chromatin structure has been chosen as a treatment target by the majority of epigenetic challenges. Most of the isoform-selective HDAC-inhibitors could have an importance in the treatment of cancer, Huntington's disease, sickle cell disease, or CVDs [198, 199].

Epigenetic tags can be affected by modifiers of methylation. DNA methylation status alter the function of target atheroprotective genes, such as ER α and ER β genes in atherosclerosis [76]. Human coronary atherosclerotic tissues contain hypermethylated ER α and ER β genes. This hypermethylation status could be demethylated by using epigenetic inhibitors such as DAC. DAC could upregulate the expression of silenced ER α and ER β genes [75]. Therefore, therapeutic options could be used in the treatment of atherosclerosis by changing the epigenetic modifications.

DAC is a DNA methylation inhibitor. It has worked as a successful treatment option in hematological diseases and malignancies. As portrayed by cardiovascular research, DNA methylation inhibitor promotes the differentiation of cardiomyocytes from mesenchymal stem cells at low frequencies [200, 201]. DAC was given prime importance after this finding. Unluckily, myeloid suppression and induction of cardiomyocyte cell death are the toxic affects imposed by DAC on behalf of its potential benefits. Zebularine is another cytidine analog. It produces less toxicity than DAC [202]. This property of zebularine promotes its use in studies on cardiomyocyte differentiation from ESCs. In the recent study, Horrillo et al. demonstrated that zebularine promotes cardiomyocyte differentiation from ESCs with increased expression of cardiac-specific genes [203]. However, using of this knowledge in the development of stem-cell-based therapy for degenerative cardiac diseases is still elusive.

In addition, collagen type XV A1 (COL15A1) is hypomethylated in the process of aortic SMCs proliferation. DAC treatment induces aortic proliferation by inhibiting DNMTs and demethylating COL15A1 [204].

There are many documents which revealed that epigenetic mechanisms could be limited by HDAC and HAT inhibitors in CVDs. Trichostatin A and valproic acid, HDAC inhibitors, upregulated CYP7A1 expression and reduced plasma cholesterol levels in LDL-knockout mice [205]. Furthermore, it has been defined that Trichostatin A increased the ER α and ER β levels in SMCs and ECs [76]. The other study demonstrated that reduction of HAT activity by inhibition of the co-activators nuclear cap-binding protein subunit 1 and p300 HAT reduced cardiac hypertrophy [105]. Curcumin is one of the inhibitor of HAT activity [206]. It has been found that Curcumin prevents ventricular hypertrophy and preserved systolic pressure by inhibiting p300 HAT activity in an animal model of HF [104].

MiRNA biological network in the cardiovascular system plays an important role for CVD prevention, diagnosis, and therapy [207]. MiRNAs seems have critical importance in the understanding of the diagnosis and therapy of CVDs, especially diagnostic rather than the therapeutic approach [208].

A number of miRNAs are supposed as biomarkers for the diagnosis of MI. Many reports showed that miR208a-b was upregulated in blood and heart tissue [209, 210]. Furthermore, miR1 and miR499 were demonstrated as biomarkers for MI [134, 210].

Fukushima and colleagues profiled plasma miRNA levels in patients with HF. They showed decreased plasma concentration of miR126 in patients vs healthy subjects, it is also negatively correlated with Brain Natriuretic Peptide (BNP) plasma levels. BNP is a biomarker of HF and so increased miR126 levels can be a biomarker for HF [141]. In addition, miR508-5p could be defined as novel diagnostic and therapeutic miRNAs for HF [211].

MiRNAs have been recently studying as likely therapeutic targets. It is supposed that miRNAs could be novel clinical therapeutic approaches for CVDs. Preclinical studies are being done on miRNAs and CVD treatment. Despite markedly advances, in vivo studies just remain scientific and therapeutic challenge [130].

Several animal models have been generated for therapeutic approaches in CVDs. It has been shown that treatment of antagomir-92a protects against endothelial activation and dysfunction and CAD in mice [212]. MiR155 induces the cardiac hypertrophy. So, miR155 inhibition might provide clinical therapeutic strategies for cardiac hypertrophy and HF [213]. Also, it has been shown negative correlation between silencing of miR329, miR487b, miR494, and miR495 and in arteriogenesis [214]. Recently, it is found that miR146a/b could be modulated by combined therapy [215]. Furthermore, pharmacological compounds can be used for modulation of miRNAs as an effective therapy [130]. Montgomery and colleagues silenced the miR208a by Anti-miR and improved heart function and surviving in HF progression in rats [216]. In addition, it has been shown that downregulation of miR1 could be therapeutic target against acute MI [217].

More human and animal studies are still few, so it is needed further investigations of miRNAs to improve therapeutic advance in CVDs.

At present lncRNAs have been studying to understand the function of these molecules in heart development and CVDs. So, future studies should reveal diagnostic and specific therapeutic benefits in CVDs.

Since 2012 when it was reported at the American Heart Association Scientific Sessions regenerative medicine is now a prominent actor of CVD research [218]. Genome wide

association studies and epigenetics are major actors of both basic and clinical CVD research. There are ongoing trials and basic science research projects to establish the part of epigenetics in regenerative medicine. There is massive potential of induced pluripotent stem cells (IPSCs) in altering the way we approach CVD. Pluripotent stem cells could have a role in regenerative medicine and individualized CVD therapies [218].

In order to alter the programming of somatic cells in the production of IPSCs, Sun et al. proposed the use of methods using microRNA. Sustaining pluripotency, specific cell lineage and modification of chromatin by epigenetics requires microRNA [219].

The other advanced application of regenerative medicine is utilization of a distinct biologic framework as the foundation of an epigenetically-modified, surgically insertable graft of different tissues. Jungebluth et al. portrayed this in their case of human tracheobronchial transplantation. The utilization of this method for vascular or other CV graft may effortlessly be visualized [220].

Integration and solution of these kind of problems fits perfectly for the application of the principles of epigenetics in regenerative medicine.

CONCLUSION

CVDs have a complex pathophysiological basis. Multiple genetic and environmental risk factors are associated with CVDs. Modification of epigenetic marks are one of the risk factors of CVDs. Many epigenetic alterations may play key roles in initiation and progression of CVDs. Definition of the epigenetic mechanisms required to contribute to CVDs will identify strong significant contributions for novel and targeted therapeutic approaches in CVDs. Success of these clinical approaches could have an important impact on a large fraction of the human CVDs. Future studies will also clarify the detailed epigenetic modifications linked to CVDs and use this knowledge to prevent of CVDs.

ABSTRACT

Extensive characterization has been performed on the genes and genetic mutations that are involved in spermatogenesis and male infertility, but the vast role of the sperm's transcriptome and epigenome in male reproduction has yet to be completely explored. Recent research has established that epigenetic remodeling of the sperm is necessary for development and for its function following fertilization. The histone- retained regions of the sperm have been recently shown to carry the bivalent marks of activating histone H3 lysine K4 trimethylation and the repressive H3 lysine K27 trimethylation. These bivalent histone marks facilitate the dynamic changes in stage-specific gene expression during sperm development. The paternal epigenome bears unique and important epigenetic modifications determined to be potentially important to the developing embryo, but the complete scope of its contribution is still emerging. Additionally, advances in assisted reproductive techniques have also suggested that alterations in the epigenetic profile in infertile men are transmitted to the developing embryo. This review will highlight the latest advances in epigenome profiling of the chromatin modifications during the development of immature to a mature sperm as well as provide a glimpse into the future role of epigenetic mechanisms in the generation of new germ cells/gametes from induced pluripotent stem cells, to treat male infertility.

ABBREVIATIONS

AR	Androgen receptor
ART	Assisted reproductive technology
AZF	Azoospermia a/b/c
BRDT	Bromodomain testis-specific protein
CFTR	Cystic fibrosis transmembrane conductance regulator
DAZ	Deleted in Azoospermia
DMR	differentially methylated regions
DNMT1/3a/3b	DNA methyltransferase
ESC	embryonic stem cells
HAT	histone acetyltransferases
HDAC	histone deacetylases
ICSI	Intra-cytoplasmic sperm injection
IGF2	Insulin-like growth factor
IVF	In vitro fertilization
KLF4	Krueppel-like factor 4
iPS/iPSCs	Induced pluripotent stem cells
MTHFR	methylene tetrahydrofolate reductase
MIWI2	PIWI protein
PRM1/2	Protamine 1/2
PGC	Primordial germ cells
PGCLC	primordial germ cell-like cells
SAM	S-adenosyl methionine
TP	transition proteins
OCT4	octamer-binding transcription factor 4
SCOS	sertoli cell-only syndrome
SSC	spermatogonial stem cells
SNRPN	small nuclear ribonucleoprotein polypeptide

INTRODUCTION

1. SPERM CELL DEVELOPMENT

In the past, it was believed that the sperm is but a vehicle to transfer the male genome into the oocyte, but increasing evidence now suggests that sperm cells play a substantial role in initiating embryo development, and environmental influences on the paternal genome can adversely affect male fertility as well as babies conceived via assisted reproductive technology (ART) [1].

Spermatogenesis involves the precise and well-controlled differentiation of germinal cells from spermatogonia to spermatozoa [2, 7]. This highly orchestrated process is a continuous process, characterized by a pre-meiotic, meiotic and a post-meiotic stage. Spermatogonia divide by mitosis, followed by meiosis through the formation of primary spermatocytes. As spermatocytes, they replicate DNA and undergo meiosis. During the meiosis stages, pairing of homologous chromosome, recombination, replacement of somatic histones with variants occur, and finally, at the post-meiotic stage, spermatids form into compact spermatozoa [3, 4].

Active transcription occurs during the stages of spermatocytes and round spermatids, but the later stages of spermatogenesis are relatively transcriptionally inert due to the compaction of the chromatin. Transcriptional, post-transcriptional, epigenetic regulatory networks direct the multiple stages of germ cell specification, differentiation and development [5]. Sperm chromatin is essential for sperm function as well as for embryonic development; defective sperm chromatin leads to abortion, decreased fertility, loss of genomic integrity or assisted reproductive failure [6].

2. EPIGENETIC REPROGRAMMING OF MALE GERM CELLS

Epigenetics is dominantly involved in the preservation of cellular identity and lineage fidelity, through the different mechanisms of alterations in chromatin structure, modifications of DNA and histones, remodeling of nucleosomes etc. Global reprogramming of epigenetic marks, in addition to meiotic chromatin organization and recombination as well as compaction of sperm genome, in the primordial germ cells (PGC) occurs during gametogenesis and in zygote following fertilization (Figure 1) [2]. The first reprogramming event occurs in the developing gonad. The reversible nature of epigenetic processes allows for the resetting of epigenetic information in the germ cells, in order to equip the sperm and oocyte to direct embryonic and post-natal development [7].

Dynamic epigenetic alteration is central to differentiation of mammalian sperm; however, the nature of these changes largely remains unknown. Spermatogenesis is a continuous and precisely controlled process that is accompanied by a dramatic reorganization of chromatin from a nucleosomal histone-based structure to a structure largely based on protamines [8]. During the spermatogenesis process, upon histone H4 hyperacetylation, nucleosomes are disassembled, DNA breaks occur and incorporation of non-canonical histone variants is made possible [9]. Histones are widely replaced by highly basic proteins, first by transition proteins and subsequently by the two protamines PRM1 and PRM2 [10].

Upon fertilization, the products of germ-cell development, the oocyte and sperm cell, fuse to form a zygote, a totipotent structure that can develop into a whole new organism [11]. Following fertilization, histones seem to remain associated with the paternal genome, in order, to contribute to zygotic chromatin despite the extensive reorganization of the sperm chromatin. Also, the sperm DNA is decondensed from its highly compacted and transcriptionally quiescent state, and expands to the inducible state found in the paternal pronucleus [12]. The paternal histones could therefore serve as a template for the incorporation of newly synthesized histones during replication in the zygote. Accordingly, the programmatic chromatin packaging in sperm could potentially deliver epigenetic information to the oocyte and the zygote post-fertilization [13].

Figure 1. Epigenetics govern the regulation of processes from the initial stages of spermatogenesis to embryo development.

2.1. DNA Methylation

DNA methylation occurs largely on CpG islands located upstream of genes [14]. It is a process in which a methyl group from S-adenosyl methionine (SAM) is transferred to a cytosine residue to create 5-methyl cytosine (5mC). This process is catalyzed by a family of closely related DNA methyl transferases (DNMT1, DNMT3a and DNMT3b) [15]. The passive process takes place during replication of newly synthesized DNA strands by DNMT1.

The purpose of DNA demethylation in PGCs is to prevent transmission of inappropriate epigenetic information to the next generation. It is interesting to note that genome-wide methylation patterns in sperm differ markedly from that of somatic cells, highlighting the sperm-specific role of DNA methylation [8]. DNA methylation patterns are first acquired during gametogenesis. Evidence for the significance of DNA methylation for male germ cell development has been demonstrated in the mouse, where gene targeting of enzymes involved in catalyzing DNA methylation, the DNA (cytosine-5)-methyltransferases (DNMTs), results in loss of germ cell methylation, and failure of meiosis and infertility [16, 17, 18]. Recent studies have shown that mono methyl, dimethyl and trimethyl modifications of H3K4, H3K9 or H3K27 display tightly controlled temporal expression and ensure proper progression through spermatogenesis [19]. The level of H3K4 methylation peaks in the spermatogonial stem cell stage, and a targeted loss of H3K4 methylation, caused by reduction of Mll2 (an H3K4 methyl transferase) activity results in a dramatic reduction in the number of spermatocytes, suggesting that H3K4 methylation is essential for the exit from the stem cell stage and commitment to become a spermatocyte [20, 21, 22]. In contrast, H3K9 methylation and H3K27 methylation are low in the stem cell and increase during meiosis, persisting long after meiosis is complete, presumably to ensure gene-silencing [23]. Methylation on lysine 9 of histone H3 (H3K9me) is also associated with the sex chromosomes, euchromatin and heterochromatin in the late pachytene stage; however, the levels of H3K9 methylation drop upon completion of meiosis [24, 25]. This reduction in H3K9me is concurrently associated with an increase in H3K4me levels [7].

2.2. Histone Modifications

Histone modifications include the various post-translational alterations on the lysine-rich tail region of histones, especially of H3 and H4 histones [26]. However, histone acetylation, methylation and phosphorylation are more relevant during sperm development, spermatogenesis, fertilization and embryo development (Figure 2) [27].

The compactness of DNA is determined by histone proteins that are bound to DNA [28]. During the post-meiotic maturation of spermatids into spermatozoa or spermiogenesis, the genome of the male germ cell is entirely restructured. Indeed, while the core of the spermatid extends and condenses, most somatic histones are removed and replaced progressively by proteins called “transition” or TP, which are then replaced with specific nuclear proteins of sperm nucleus known as protamines [29, 30]. Protamines aid in the tight packaging of chromatin and are protective against the effects of harmful physical or chemical stressors [29]. In humans, histone to protamine transformation is considered to be incomplete, and the residual histones are highly acetylated and located in the annular region [29]. However, a small amount

of histone proteins is retained in spermatids, and chemical modification of these histones play an important role in sperm formation.

Figure 2. Epigenetic modifications involved in Sperm development.

During spermiogenesis, only 4% of the genome is retained in nucleosomes, while the rest of the histones are replaced with protamines. But the retained histones are overwhelmingly found at CpG islands near key developmental genes. The fetal germ cells contain several genes in a poised conformation, with both the H3K4me3 and H3K27me3 modifications [23, 25, 31]. Based on these findings, it can be presumed that the poised state of chromatin in germ cells are necessary for germ cell identity, to prepare for totipotency following fertilization and possibly to prevent DNA methylation at key developmental promoters [22].

The acetylated histone marks H3K4ac and H3K39ac are associated with transcriptional activation. There is growing interest in histone acetyl transferase (HAT) and histone deacetylase (HDAC) proteins involved in histone acetylation and spermatogenesis because they modulate gene expression and serve as a trigger for chromatin reorganization and remodeling [19, 32]. Waves of histone acetylation occur throughout human spermatogenesis. For example, hyperacetylation of histone-H4 was observed in spermatogonia, pre-leptotene spermatocyte and spermatids [19]. It facilitates the interaction of non-histone chromosomal proteins, such as transcription factors, with the chromatin. In spermatids, hyperacetylation of histone-H4 recruits bromodomain protein (BRDT) that triggers nuclear reorganization. Recent studies have demonstrated a statistically significant reduction in the percentage of spermatogonia with Hypac-H4 or Lys12ac-H4 [33]. Furthermore, hypac-H4 is believed to trigger nuclear reorganization and probably facilitate exchange of histones by protamines that allow condensation of the spermatid nucleus [33]. Another study demonstrated increased acetylation of histone H4 may be associated with a histone-to-protamine substitution, suggesting specific relationship between histone H4 modification and gene expression during spermatogenesis [19].

Every stage of spermatocyte development shows specific patterns of H4 modification. In pre-leptotene spermatocytes, the expression of H4me, H4K20me2, H4K5ac, H4K8ac and H4K12ac was high, and that of H4me3 was relatively low. Whether acetylation itself is only associated with gene activation is still not certain because it has been recently shown that

protamines also contain acetyl groups. Studies have also alluded to other post-translational modifications, such as S42 and K49 acetylation of protamine-1 and K64 acetylation on protamine-2 [34]. The fact that protamines carry marks associated with transcriptional activation is intriguing, as these proteins are thought to ensure tight packaging of the DNA in sperm cells and contribute to transcriptional silencing. Although histone acetylation is a characteristic feature of transcriptional active genes, it is known that spermatozoa are transcriptionally inactive. This obvious inconsistency resulted in the hypothesis that histone acetylation represents an epigenetic mark that is transmitted from sperm to oocyte and involved in the regulation of gene expression in the early embryo [34].

2.3. Chromatin Remodeling

Chromatin remodeling is a process in which ATP-dependent chromatin remodeling complexes (SWI/SNF, ISW1 and MI-2) use energy to alter the location and structure of nucleosomes [35]. The remodeling process activates or represses gene expression, as required for proper meiotic development and maturation of gametes [28]. It is a critical step in gamete development, and the compacted structure of the chromatin transmits vital information to the embryo to guide it through development. The lack of proper DNA packaging in sperm has been associated with infertility in mice [36]. During the chromatin repackaging process in spermatogenesis, about 85% of the histones are replaced by protamines [12]. In the initial stages of spermiogenesis, histones are hyperacetylated and undergo other modifications [36]. Subsequently, at the final stage of spermatogenesis, the nucleosomal structure is progressively disassembled, then replaced by transition proteins (TPs) and finally by protamines [37].

The incorporation of protamines into sperm chromatin induces DNA compaction that is important for the formation of spermatozoa [30]. However, it is known that protamines are phosphorylated before binding to DNA and that substantial dephosphorylation takes place concomitant with nucleo-protamine maturation. Indeed, mutation of the calmodulin-dependent protein kinase Camk4 that phosphorylates protamine 2, results in defective spermiogenesis and male infertility [38]. At fertilization, the mature sperm cells are packaged densely with protamines, whereas maternal genome is packaged with histones. Subsequently, upon fertilization, the highly compact nucleoprotamine structure must be unpacked and reorganized into a nucleosomal structure [39]. Recent studies have shown that epigenetic errors in these processes are a possible cause of male infertility. Both protamines 1 and 2 are essential for sperm function, and the haploinsufficiency of either P1 or P2 results in a reduced amount of the respective protein, abnormalities in the structure of the chromatin, DNA damage and infertility [28]. Furthermore, it is known that the optimal protamine-1 to protamine-2 ratio (P1/P2 ratio) is critical and well regulated [40]. Indeed, the P1/P2 ratio in fertile men ranges from 0.8–1.2 and deviation from this ratio has been shown to lead to infertility [41]. A change in either direction of this ratio adversely affects semen quality, DNA integrity and fertility in men. Patients with abnormally depressed or elevated P1/P2 ratios are characterized by poor sperm concentration, motility and morphology as well as decreased fertilization capabilities. Impaired spermatogenesis has been reported to be associated with aberrant H4 acetylation [42]. A study by Sonnack et al., showed that men exhibiting qualitative or quantitative infertility have significantly decreased levels of histone H4 acetylation associated with impaired spermatogenesis [43]. Hyperacetylation of histone H4 is required in the transition from histones to protamines. This step decreases the affinity of the interaction between the sperm histones and DNA to allow for the exchange of transition proteins to occur [28]. H4 hyperacetylation

was also observed in infertile men exhibiting sertoli-cell-only syndrome (SCOS) [44]. A significant difference in transcript expression of chromatin remodeling factors between normal spermatogenesis and the stage of round spermatid maturation arrest has been found in a previous study, suggesting impaired epigenetic information and aberrant transcription during sperm development. This could represent one possible reason for the developmental arrest of round spermatids [45].

2.4. Small RNAs

Spermatozoa contain numerous populations of RNAs. Small RNAs that have been enriched in sperm include microRNA (miRNA), endogenous small interfering RNAs (endo-siRNA), small non-coding RNA (sncRNA) and PIWI-interacting RNAs (piRNAs). Alterations in any one of the populations of RNAs in sperm indicate sperm abnormalities [3]. The importance of piRNAs in germline is very evident through their role of silencing of transposable elements during DNA demethylation in PGCs [46]. Mice knockout studies, where Dicer 1 was specifically deleted in spermatogonia, revealed prominent defects during haploid differentiation, specifically, in nuclei elongation and chromatin organization. Speculated roles for endo-siRNAs in germ cells include silencing and regulation of heterochromatin formation and maintenance. Among the piRNAs, MILI and MIWI2 together with pre-pachytene piRNAs, participate in silencing of transposable elements in fetal and neonatal germ cells. In the absence of these piRNAs in mice, it was shown that transposons were uncontrollably expressed, leading to meiotic arrest and sterility eventually [47].

3. EPIGENETIC DYSREGULATION: MALE INFERTILITY

3.1. Male Infertility

Human infertility, caused largely by a deficiency of sperm cells, is a major health problem that affects ~15% of couples globally [48]. It is a multifactorial syndrome encompassing a wide variety of disorders (Figure 3). Anatomic defects underlying male infertility include varicocele, vesicular damage due to torsion, obstruction of testicular sperm passage and ejaculatory failures, genital tract infections, gametogenesis dysfunction, molecular genetics disorders, endocrine disturbances and immunologic problems [48-50]. Additionally, factors such as life style, environment and smoking have also been reported to affect gamete and embryo development [51, 52]. In order to understand potential regulatory mechanisms involved in disease pathogenesis, it is essential to identify the molecular genetic factors involved in the etiology and physiology of male infertility.

Deletions in the Azoospermia Factor a, b and c (AZFa, AZFb and AZFc) regions of the long arm of the Y chromosome have been identified as the most common cause of Y-linked male factor infertility, particularly spermatogenic failure [53, 54]. In addition to Y-linked genes, many autosomal and X-linked genes such as CFTR, androgen receptor (AR) genes, estrogen receptors (ESR) genes, ubiquitin-specific protease-26 (USP26) gene, are also

necessary for normal sexual development, testis determination, testis descent, spermatogenesis and eventually fertility in men [48, 55].

Figure 3. Most common causes of male infertility. Male Infertility is a multifactorial disease, with varied causative factors including genetic, molecular, epigenetic, immunological, environmental and life styles.

The advent of new technologies has spurred research on the role of epigenetics in spermatogenesis and male infertility. Epigenetics refer to process of gene regulation devoid of changes in DNA sequence [56]. Epigenetics is dominantly involved in the preservation of cellular identity and lineage fidelity, through the different mechanisms of alterations in chromatin structure, modifications of DNA and histones, remodeling of nucleosomes etc. Studies have demonstrated that numerous genes can be regulated through epigenetic mechanisms in the testes, indicating a direct influence of epigenetic mechanisms on the process of spermatogenesis, sperm development or maturation, fertilization process as well as male fertility [27]. It has become increasingly clear that epigenetic regulation of gene expression is critical during spermatogenesis and fertilization process [57].

Studies have made it abundantly clear that, in fathers exposed to environmental toxins or pesticides, sperm quality and chromatin integrity can be negatively affected through the primordial germ cells (PGCs), where there are some protected portions of the genome containing repetitive elements and single copy sequences that have the potential to transmit DNA methylation across generations or during differentiation, from PGCs to spermatogonia, de novo methylation occurs at imprinted loci or during development from spermatogonium to

spermatocytes and during reprogramming that happens at fertilization, through the 4-10% of retained histones [58-60].

3.2. Genomic Imprinting

Genomic imprinting, namely, the expression of alleles in a sex-specific manner, is characterized by epigenetic modifications including differential methylation in the CpG islands in either the maternal or paternal alleles [28]. It determines which genes from the parental and maternal genomes are expressed in the embryo and is critical for normal development [61]. Parental imprints are erased in the PGCs of the developing embryo, and re-established during gametogenesis in a sex-dependent manner, maintained through fertilization, pre- and post-implantation embryonic development [62]. Imprint re-establishment occurs at late fetal stages in male germ cells and after birth in growing oocytes [64].

In humans, fetal spermatogonia seem to be mostly unmethylated at *H19* differentially methylated regions, although spermatogonia in adult testis demonstrate significant methylation in this region [28]. Imprinted genes, including the paternally imprinted *GTL2* and *H19* loci, have been previously examined by Kobayashi et al., in 97 infertile men. The importance of genomic imprinting during spermatogenesis has been reinforced by the association of decreased methylation of the paternal *IGF2/H19* imprinting control region 1 (ICR1) and *GTL2* imprints in spermatozoa of men with disturbed spermatogenesis [60]. In another study by Poplinski et al., fertile men had a high degree of *IGF2/H19* ICR1 and a low degree of *MEST* methylation [64]. Low sperm counts were clearly associated with *IGF2/H19* ICR1 hypomethylation and, even stronger, with *MEST* hypermethylation. These results suggest that idiopathic male infertility is strongly associated with imprinting defects at *IGF2/H19* ICR1 and *MEST*, with aberrant *MEST* methylation being a strong indicator for sperm quality. Previous studies have also suggested that Prader-Willi Syndrome and Angelman syndrome are caused by the specific loss of paternally expressed genes [2].

ART techniques such as ICSI and round spermatid injection (ROSI) may increase the incidence of imprinting disorders and adversely affect embryonic development by using immature spermatozoa that may not have established proper imprints or global methylation yet. Andrologists have voiced concern about concealing reproductive defects through ART that might have negative consequences at the epigenetic level [2].

3.3. DNA Methylation

DNA methylation occurs largely on CpG islands found upstream of genes [14]. It is a process in which a methyl group from S-adenosyl methionine (SAM) is transferred to a cytosine residue to create 5-methyl cytosine (5mC). This process is catalyzed by a family of closely related DNA methyl transferases (DNMT1, DNMT3a and DNMT3b) [65].

The establishment and maintenance of correct DNA methylation patterns is essential for fertility, embryo development and viability of the offspring. Abnormal methylation patterns in human spermatozoa have been reported in men with infertility and low sperm counts [66]. Recent studies have demonstrated that CpG methylation occurs in selected promoters of the fertile group, while methylation levels in subfertile patients vary considerably [64]. Sperm

DNA methylation levels are related to conventional sperm parameters, as well as, sperm chromatin and DNA integrity [67]. Recently, hypermethylation of promoters of several genes including *MTHFR*, *PAX8*, *NTF3*, *SFN*, *HRAS*, *JHM2DA*, *IGF2*, *H19*, *RASGRF1*, *GTL2*, *PLAG1*, *D1RAS3*, *MEST*, *KCNQ1*, *LIT1* and *SNRPN* have been reported to be associated with poor semen parameters or male infertility [28]. Improper DNA methylation of various genes has been implicated in abnormal semen parameters, as well as several instances of male infertility. Houshdaran et al., demonstrated for the first time, that poor sperm concentration, motility and morphology were associated with broad DNA hypermethylation across a number of loci including *PLAG1*, *DIRAS3*, *MEST*, *PAX8*, *NTF3*, *SFN* and *HRAS*. They suggested that the underlying mechanism for these epigenetic changes may be improper erasure of DNA methylation during epigenetic reprogramming of the male germ line [68]. In another study by Khazamipour et al., 53% of men with nonobstructive azoospermia revealed hypermethylation of the *MTHFR* promoter, while none of the men with obstructive azoospermia exhibited hypermethylation of this gene promoter, suggesting that *MTHFR* hypermethylation is a specific epigenetic aberration that may specifically contribute to certain types of male infertility [69]. In addition, Wu et al., in a study reported that hypermethylation of *MTHFR* gene promoter in sperm was associated with idiopathic male infertility [70]. Abnormal DNA methylation of *H19* and *MEST* imprinted genes has also been shown to be associated with oligozoospermia, suggesting that spermatogenesis may be particularly vulnerable to changes in the methyl pool brought about by deficiency in *MTHFR* enzyme [71]. Hammoud et al., examined CpG methylation patterns in infertile (oligozoospermic and those with abnormal protamine ratios) and fertile donors at seven imprinted loci including *LIT1*, *MEST*, *SNRPN*, *PLAGL1*, *PEG3*, *H19*, and *IGF2* [72]. At six of the seven imprinted genes, the overall DNA methylation patterns were significantly altered in both infertile patient populations. They demonstrated a link between abnormal spermatogenesis and abnormal methylation of genes. Contradictory reports demonstrated high methylation at the *H19/IGF2* ICR1 locus and low methylation at the *MEST* locus in normozoospermia in one study, while another study revealed low methylation of the *H19/IGF2* ICR1 locus and high methylation of the *MEST* locus in association with low sperm concentrations [64]. Similarly, Boissonnas et al., found that many patients with teratozoospermia and oligoasthenoteratozoospermia exhibited hypomethylation at variable CpG islands at the *H19* locus [73]. However, recent studies have shown that hypermethylation at *MEST* was more strongly linked with poor sperm quality than hypomethylation at *H19/IGF2* ICR1 [28]. They suggested that sperm from infertile patients, especially those with oligospermia, may carry a higher risk of transmitting incorrect primary imprints to their offspring, highlighting the need for more research into epigenetic changes, when considering ART. The X-linked *RHOX* cluster encodes a set of homeobox genes that are selectively expressed in the male and female reproductive tract. Some members of the *Rhox* cluster are crucial for normal spermatogenesis, germ cell survival and male fertility. A recent study has demonstrated that the human *RHOX* gene cluster serves as an excellent marker for idiopathic male infertility. This study revealed a strong association between human *RHOX* cluster hypermethylation and the severity of poor sperm quality [74]. It appears that, DNA methylation directly represses the transcription of human *RHOX* gene family members. Incorrect DNA methylation of the *DAZL* promoter CpG island has been shown to be associated with defective human sperm [66]. *DAZ* gene family is crucial for normal spermatogenesis, as deletion of *DAZ* is estimated for 10% of cases of men with spermatogenic defect [75]. Targeted disruption of *DNMTs* genes in mice resulted in embryonic lethality and infertility [76]. Hammoud et al.,

showed a significant association between male factor infertility and alterations in sperm DNA methylation at imprinted loci [72]. They reported that patients with male factor infertility had significantly increased methylation alteration at LIT1, MEST, SNRPN, PLAGL1, PEG3, H19, and IGF2 genes [72]. In another study, DNA methylation at MEST gene was significantly associated with oligozoospermia, decreased bi-testicular volume and increased FSH levels [79]. Increased abnormal DNA methylation in the ART sample (41%) has been reported previously [80]. The reduced DNA methylation of the H19 ICR has been reported negatively correlated with sperm concentration [81]. A significant decrease in DNA methylation at the H19 DMR (differentially methylated regions) was found in testicular sperm of azoospermic men compared with proven fertile men [16]. In another study by Vieweg et al., sperm DNA methylation of normozoospermic men displayed low standard deviation, while a higher variability in the percentage of DNA methylation was detected in the promoters of subfertile men [68]. These data suggest that abnormalities in DNA methylation level in human sperm not only impact on sperm parameters quality and male infertility, but it could also represent a new approach to investigate the fertilizing ability of sperm in an assisted reproduction procedure, especially when sperm samples with normal characteristics are used [82].

4. EPIGENETICS IN ART (ASSISTED REPRODUCTIVE TECHNIQUES)

Assisted Reproductive technology (ART) includes all artificial methods used to achieve pregnancy [83]. Although a boon to infertile couples, ART-related manipulations to oocytes and embryos, have to be reviewed and designed with caution, as they coincide with the development of sex-specific genomic imprints [84]. The invasive as well as the non-invasive procedures performed during ART, including hormonal stimulation, egg retrieval, intracytoplasmic sperm injection (ICSI), micro-manipulation of gametes, *in vitro* fertilization (IVF), *in vitro* oocyte maturation, exposure to culture medium and centrifugation could potentially harm the early embryos and gametes. The process of ART coincides with crucial developmental phases of the pre-implantation embryo, and is therefore, implicated in inducing epigenetic changes that could affect fertility in subsequent generations and result in the birth of children with a higher risk of infertility, congenital abnormalities and morbidity [49]. It is thus imperative for the clinicians involved in the treatment of these couples to initiate genetic evaluation and counseling prior to any therapeutic procedures.

Until recently, the main evidence that ART like IVF/ICSI causes abnormalities in offspring, was corroborated by low birth weight babies, or premature births [83, 84]. Zhang et al., utilized microarray studies to show that poor perinatal outcomes in ART children arise from changed expression of genes involved in immune response, cell differentiation, compared to control patients [85]. But more recent investigations have shed light into differential expression of DNA methylation-associated genes that have been detected in offspring conceived by ART procedures. The commonly investigated list of imprinted genes for methylation-dependent disruptions include KCNQ1OT1, IGF2, SNRPN, MEST/PEG1, PEG10, PEG3, L3MBTL [87]. Children conceived from infertile couples, through ART have a higher propensity to develop imprinting disorders, since it has been shown that imprinted genes are more susceptible to environmental stresses [87]. A small but statistically significant subset of genes have altered

DNA methylation profiles in children derived through ART, and the authors [87] propose that these significant differences in gene expression could be accounted for, by either the abnormal epigenetic marks borne by infertile couples or from the ART process itself. But, overall, conflicting studies on the effects of ART on offspring have made it impossible to conclusively point to major differences between ART and normal children [88, 89].

In addition to short-term outcomes, long-term outcomes, with regard to ART-conceived children is also important to scrutinize. It is interesting to note that several studies have observed taller ART children, at the ages of 6-10 years, probably due to the pre- or early implantation factors. But, with respect to gonadal development or fertility status in ART-conceived children, there was basically no change between ART offspring and spontaneously conceived children [90, 91, 92].

5. EPIGENETIC MAKE-UP OF INDUCED PLURIPOTENT STEM CELLS/PGC FROM ADULT CELLS

In order to enhance our understanding of male reproduction and its associated diseased condition, male infertility, it is crucial to recapitulate gametogenesis and embryogenesis, *in vitro* [93, 94]. The last decade in reproductive research has seen important strides in this field using induced germ cells. The *in vitro* induction of germ cells from autologous iPS (induced pluripotent cells) and embryonic stem cells will also function as an additional route to conceive, for infertile couples, who cannot produce any gametes of their own [94]. Needless to say, the differentiation of human iPS cells will also enable in the molecular elucidation of diseases in gynecology, pediatrics and obstetrics.

Human IPS cells can be generated from somatic cells by the ectopic expression of OCT4, SOX2, KLF4 and c-MYC [95]. Recently, additional reports have demonstrated that human iPS cells can be induced to differentiate into the PGCs, gonocytes, spermatocytes, and into round spermatid –like cells [94]. It is however, important to note that PGCs derived from iPS cells have shown inefficient imprinting, as well as a propensity to acquire trisomies in chromosomes 12 and 17, possibly hinting to epigenetic instabilities. Additionally, human iPS cells seem to acquire higher number of CNVs, and revealed copy number variants at early passages compared to human ES cells. High-resolution methylation studies have also suggested that some iPS cell lines possess somatic memory, raising concerns about aberrant methylation and imprinting [10, 11, 18].

As a landmark discovery in this field, Saitou et al., accomplished the difficult task of generating PGC-like cells (PGCLC) from mouse ESC/iPSC cells. In order to prove that these PGCLCs could generate germ cells, they placed the PGCLCs into neonatal mice lacking their own germ cells. Very interestingly, mature sperms were produced from the testes, and could even be fertilized to produce their own offspring [95]. Though the PGCLCs could form functional sperm, there were minor differences in PGCLC-derived sperms compared to PGC-derived sperms [97]. But it is necessary to proceed with caution, since it is very likely that, they will be subject to genetic/epigenetic instabilities during iPS cell generation process, since the generation of such germ cells seem to occur against the Weismann barrier (hereditary information moves only from germ cells to somatic cells) [94].

An impairment of epigenetic reprogramming in germ cells can lead to loss of germ cells, faulty embryos or defectively developed offspring from these faulty embryos. In mice, during reprogramming of PGCs, they initiate a transcriptional network for pluripotency by predominantly acquiring epigenetic marks such as histone H3 lysine 9 dimethylation (H3K9me2), histone H3 lysine 27 trimethylation (H3K27me3) and demethylation of 5-methylcytosine, in addition to, silencing somatic programs [97, 98]. As a result, the PGCs acquire low levels of genome-wide 5-methylcytosine.

Recent progress in germ cell induction could lead to a new form of ART, where patients with no viable gametes will have the opportunity to produce fertile spermatozoa from autologous iPS cells, which can subsequently be used for IVF/ICSI. Utilizing spermatogonial stem cells (SSCs) from autologous iPS cells could also initiate in vivo spermatogenesis in otherwise infertile males [99].

CONCLUSION

The latest and most promising development is the creation of the first human artificial primordial germ cells (PGC) from reprogrammed skin cells by stem cell biologist Mitinori Saitou's group [100]. Initial studies performed on these artificial PGC's showed that their epigenetic and protein profiles were very similar to those of primordial germ cells obtained from aborted fetuses. In the next step in these studies, sperm or eggs were generated from these artificial PGC's in mice. It is interesting to envisage the future where these iPSc will be utilized to treat male infertility [101].

A conceivable future for the fertility treatment field will be to obtain sperm cells or eggs cells derived from skin cells of sterile men or women, which could then be a viable option to enable infertile couples to conceive, albeit, with the associated ethical concerns [102]. This technology will greatly benefit patients suffering from idiopathic male infertility, as well as the male cancer survivors. But, in order, to maximally benefit from these exciting techniques, it is imperative to gain a better understanding of the epigenetic modifications that occur during the generation of these iPSc cultures, as well as better investigate the imprints of the sperm chromatin, on a long-term basis in offspring [82].

Chapter 65

EPIGENETICS, INFLAMMATION AND INFLAMMATORY RELATED-DISEASES: A GENERAL LOOK

Müge Sayitoğlu* and Yücel Erbilgin

Istanbul University, Institute of Experimental Medicine,
Department of Genetics, Istanbul, Turkey

ABSTRACT

Epigenetic is defined as the study of mitotically and/or meiotically heritable changes in the gene function without changing DNA sequence and playing crucial roles both in normal development and human diseases. The molecular basis of epigenetic process consists of histone modifications, DNA methylation, positioning of histone variants, and non-coding RNAs. Genome-wide patterns of DNA and chromatin modifications together called as 'epigenomes'. Epigenomes undergo precise, coordinated, reversible changes through the developmental stages and so contributes to the lineage and tissue specific expression of genes. In addition to the tissue specific impact, environmental factors such as nutrients, toxins, infections and hypoxia can also influence epigenomes. Distinct or global changes in the epigenetic landscape are hallmarks of chronic inflammation associated diseases. Alteration in methylation status of CpG sites, monoallelic silencing, and other epigenetic regulatory mechanisms have been observed in key inflammatory response genes. Epigenetic changes including DNA methylation, histone modification and noncoding RNA expression, were found associated with acute and chronic inflammatory disorders. Recently, therapies targeting epigenetic mechanisms are trending options for the treatment of chronic and degenerative disorders. Epigenetic drugs that are applied on animal models and some clinical trials are displaying positive therapeutic effects. Not only mono therapies but also combined usage of HDAC or DNMT inhibitors could be the next step for the epigenetic therapeutic modulations. Scope of this chapter is to provide an overview of the epigenetic modifications in inflammation and inflammation driven diseases.

ABBREVIATIONS

DNA	deoxyribonucleic acid
RNA	ribonucleic acid
CpG	cytosine-guanine nucleotides
DNMT	DNA methyltransferases
SLE	systemic lupus erythematosus
RA	rheumatoid arthritis
MS	multiple sclerosis
HMTs	histone methyltransferases
HDMs	demethylases
HATs	histone acetyltransferases
HDACs	histone deacetylases
LncRNAs	Long noncoding RNAs
miRNA	microRNA
T1D	type 1 diabetes
CVD	cardiovascular diseases
IBD	inflammatory bowel disease
CD	Crohn's disease
UC	ulcerative colitis
ACPA	against citrullinated peptide antigens
RASFs	RA synovial fibroblasts
PBMCs	peripheral blood mononuclear cells
5-azaC	5-azacytidine cytosine
IFN	type 1 interferon
PADI2	peptidyl arginine deiminase type 2
MBP	myelin basic protein
ROS	reactive oxygen species
HIV	human immunodeficiency virus
EBV	Epstein Barr virus
SIRS	systemic inflammatory response syndrome
SSI	severe systemic inflammation
RNS	reactive nitrogen species
UVB	ultraviolet B
JAK	Janus-activated kinase
MAP	mitogen-activated protein
DMV	DNA methylation valleys

1. INTRODUCTION

Inflammation (Latin, *inflammatio*) is a part of the complex biological protective response of the body that involves immune cells, blood vessels, and molecular mediators. Inflammation develops acute or chronic response of immune system and it is modulated by genetic, epigenetic, macrobiotic and environmental events. Although many variations exist among

inflammatory diseases, a consistency occurs in local and systemic acute inflammation (like abscess and sepsis) and chronic inflammation like metabolic syndrome of obesity, cancer, atherosclerosis, autoimmunity, and aging.

One of the earliest reports which is suggested by a Roman physician named Cornelius Celsus, therein described patient symptoms against to tissue injury were *rubor* (redness), *tumor* (swelling, caused by increased permeability of the microvasculature), *calor* (heat), and *dolor* (pain). After centuries, scientists have begun to understand the physiological and cellular basis of inflammation. The inflammatory cells are not only important for host defense against pathogens; but also they play beneficial roles in tissue maintenance and homeostasis through the process of phagocytosis. Acute inflammation occurs over seconds, minutes, hours, and days, and chronic inflammation occurs over longer times. Inflammation is mainly described by redness, heat, pain and swelling, against pathogens, damaged cells, irritant and/or tissue repair/healing. Inflammatory response can be vascular or cellular. During vascular response histamine mediated hyperemia occurs, blood vessels dilate, fluid moves into tissue platelets forms a clot to trap the injurious agent. In the cellular response, white blood cells move to the site of the injury (called chemotaxis), neutrophils, monocytes/ macrophages, eosinophils, basophils and lymphocytes involve in the inflammation process [1, 2]. Inflammation has a slow onset, persists for a long period of time, and becomes chronic. The symptoms in chronic inflammation are not as severe as in acute inflammation, but the condition is persistent. Chronic inflammation is associated with a group of multifactorial complex disorders such as cancer, diabetes, neurological, cardiovascular and pulmonary disorders that will be discussed further.

Stages of inflammation can change in hours so the process needs a strict gene expression regulation. During the basal state, genes are repressed until a diverse receptor system, like toll-like receptors (TLRs), senses a threat. Whenever a threat is noticeable, cells rapidly transcribe pro-inflammatory genes to induce acute inflammation. If the threat is transient, genes return to the basal state within hours. If it is severe, the incitement phase is replaced within 4-6 hours by a gene-specific epigenetic reprogram that may endure days to weeks. Duration may extent up to 21 days in human. This sustained epigenetic regulation period produces variable inflammatory clinical phenotypes and predicts outcome [2].

Nuclear factor kappa B (NF- κ B) pathway is the first outstanding molecular mechanism, when we focus on to the molecular bases of inflammation. Canonical NF- κ B pathway has complex roles in innate immunity, inflammation and oncogenesis, which is conserved in all multicellular animals [3]. As a part of the immune defense, NF- κ B activation leads to target and eliminate transformed cells [4]. Microbial infections, TLR activation and proinflammatory cytokines such as interleukine (IL)-1 and Tumor Necrosis Factor-alpha (TNF- α) activate NF- κ B pathway. This activation induces the expression of inflammatory cytokines, adhesion molecules, key enzymes of prostaglandin synthase pathway (COX-2), nitric oxide (NO) synthase, angiogenic factors and antiapoptotic genes [5]. Termination of the transcriptional activity of NF- κ B is mainly achieved by NF- κ B, up regulating its own inhibitors such as I κ B α , A20 and CYLD [6, 7]. I κ B α enters the nucleus and removes NF- κ B from the DNA and sends it to the cytosol. In acute inflammation, this self-regulation usually ends with complete deactivation of NF- κ B. However, in chronic inflammatory states, the persistent presence of NF- κ B activating stimuli seems to outperform the inhibitory feedback circuits, rooting to an increased constitutive activity of NF- κ B. Depending on the accessibility of the genome regulated by epigenetic and genomic alterations, different transcription factors can be expressed

after eNF- κ B activation. The crosstalk between different pathways leads development of cancers and other diseases [1, 3].

The importance of the interconnection between germ line DNA and epigenetic modifications in inflammation is still emerging. The inflammatory regulatory response requires complex regulatory networks at genetic and epigenetic levels. Thousands of inflammation and innate immunity genes contribute directly or indirectly in acute or chronic inflammatory processes. Transcription factors of the NF- κ B, FOXP3, IRF, STAT families including epigenetic phenomena, play critical roles in the regulation of inflammatory genes. The proposed epigenetic mechanisms regulate acute and chronic inflammation in different ways. The epigenetic silencing state does not exist during chronic inflammation and the reason for this paradox is unknown, but it has important therapeutic implications. Therefore, we investigate the effect of epigenetic modifications in inflammation and related diseases as below.

1.1. DNA Methylation and Inflammation

DNA methylation, a dynamic process involving methylation and demethylation events, occurs in different regions of the genome and is extremely important for embryogenesis, cellular proliferation and differentiation [8]. In eukaryotes, DNA methylation only occurs at cytosine residues and catalyzed by the DNA methyltransferase (DNMT1, DNMT3a, and DNMT3b) enzymes [9]. In DNA methylation, cytosine is converted to methyl-cytosine at CpG site and about 60% of human genes have CpG islands at their promoters. The changes in DNA methylation, such as hypomethylation mostly associated with chromosome instability and activation of transposable elements, beside that hypermethylation of promotor associated CpGs often linked with suppression of gene expression and cancers [10]. DNA demethylation is necessary for the epigenetic reprogramming of somatic nuclei and active demethylation is associated with the activation of immune cells [11, 12].

DNA methylation is the most widely studied mechanism in autoimmune diseases. A range of disease associated with chronic inflammation, including systemic lupus erythematosus (SLE) and rheumatoid arthritis (RA), display global hypomethylation associated with a concurrent decreased expression of methylation-related genes. Moreover hypomethylation patterns were also observed at interferon-regulated genes, such as *IRF5*, *IFIT2*, *STAT1* and *USP18*, in CD4⁺ T cells in the context of SLE. However, not all epigenetic alterations in lymphocytes are subject to hypomethylation. It has been reported that regulatory regions of *FOXP3* in peripheral blood CD4⁺ T cells from patients with SSc, RA and T1DM is hypermethylated, affecting the expression of key transcription factor which is required for the generation of regulatory T cells [13, 14].

Alterations in DNA methylation are known to cooperate with genetic events and to be involved in various diseases [15]. Therefore, understanding the roles of DNA methylation is important for understanding disease progression. Applications of next generation techniques have led to accumulate more data on DNA methylation in both normal and disease cells. Methylation is a reversible epigenetic mark and highly informative to described gene regulation in normal and diseased cells, and it can potentially function as a biomarker [16].

1.2. Histone Modifications and Inflammation

Histones are highly alkaline proteins that package and order the DNA into structural units named nucleosomes. Nucleosomes consist of about 146 bp of DNA wrapped 1.65 turns around an octameric histone core, comprised of 2 copies each of histones H2A, H2B, H3 and H4. Nucleosomes are stabilized by linker histones H1 and H5 [17]. The core histones have a globular domain and protruding N-terminal tails, both of which are subjected to post-translational modifications [18, 19].

There are three well studied mechanisms that modulate nucleosome structure and chromatin dependent cellular processes; core histone post-translational modifications, chromatin remodeling and composition of nucleosomes. Core histone post-translational modifications, including acetylation, ubiquitination, phosphorylation, methylation, sumoylation and ribosylation affect histone interactions, change dynamics of nucleosome and subsequently regulate gene expression. In general, acetylation of lysine in the promoter regions of histone triggers the gene expression on the other hand; histone deacetylation, biotinylation, and sumoylation inhibit the gene expression. Methylation and ubiquitination mechanisms can be activator or repressor of gene expression depending on target histone residues [20, 21]. DNA methylation and histone methylation are tightly controlled entwined events. For instance, DNA methylation requires the histone H3 N-terminal tail with an unmethylated lysine 4 (H3K4). Tri-methylation of histones H3 on lysine 9 (H3K9me3) participates in DNA methylation mediated by DNMT1 [22].

Epigenetic modifications in chromatin's structure affect gene expression such as loosely packed form of DNA which is called euchromatin, shows higher transcriptional activity in contrast, tightly packed form of DNA, heterochromatin presents lower transcriptional activity [23]. Various chromatin remodeling complexes can disrupt and remodel the nucleosome structure by increasing DNA accessibility [24]. Two groups of chromatin-modifying complexes have been described; ATP-dependent complex, covalent histone modifications. The balance of histone modifications is established and maintained by a range of enzymes including, but not limited to histone methyltransferases (HMTs) and demethylases (HDMs), histone acetyltransferases (HATs) and deacetylases (HDACs). Histone modifications are important regulators of gene transcription and modulate dynamic processes that affect nucleosomes. Long noncoding RNAs have also been shown to be necessary for targeting histone-modifying activities [25].

Aberrant histone modifications contribute to human diseases such as cancer, neurodegenerative diseases and infections. Including inflammation (IL-1 β , TNF- α , LPS ect.) many stimulants can promote histone acetylation. Histone acetyl transferases (HATs) activate inflammatory genes, whereas histone deacetylase (HDACs) activity represses the inflammatory gene expression. Promoters of pro-inflammatory cytokines (such as IL-1, IL-2, IL-8, and IL-12) are rapidly acetylated and become transcriptionally active. HDACs regulate transcription of both pro-inflammatory and anti-inflammatory cytokines via their co-repressor complexes and transcription factors such as *FOXP3*, *STATs*, *GATAs*, *ZEB1*, and *NF- κ B* [22].

In addition to nuclear function, histones also act like an endogenous signal when they locate at extra nuclear space. As a response to stress, immune cells, cerebellar neurons, Schwann cells and microglia present H2A, H2B, H3, H4, and H1 on their cell surface or cytoplasm. Levels of circulating histones as well as nucleosomes are increased in cancer, inflammation, and

infection, which suggest that histones are therapeutic targets for infectious and inflammatory disorders [26, 27].

1.3. Non-Coding RNAs and Inflammation

1.3.1. Long Non-Coding RNAs

Long noncoding RNAs (lncRNAs) vary widely in size, genomic localization, and biogenesis and can be classified according to their molecular mechanism of action. lncRNAs function through a variety of different molecular mechanisms, and most commonly play a scaffolding role to promote proper recruitment and positioning of protein regulators both in the nucleus and in the cytoplasm. Loss-of-function approaches have found that lncRNAs regulate the biology of both innate and adaptive immune cells during inflammatory responses. Some nuclear lncRNAs that contribute to the regulation of DNA methylation in the context of inflammation have been identified. Some lncRNAs implicated in histone modification, particularly methylation, that play role in processes such as cell cycle, inflammation, and senescence [28].

Some inflammation related lncRNAs and their functions are summarized below;

NeST is involved in inflammation during microbial infection, binds to the H3K4 methyltransferase component WDR5 (WD repeat domain 5) and recruits it to the *IFN γ* locus. *IFN γ* methylation increases with advancing age, *NeST* could contribute to the inflammatory response and infection in elderly.

17A is up regulated in cerebral tissues derived from Alzheimer disease patients as well as in response to inflammatory stimuli such as *IL-1 α* . *17A* is encoded within the *G-protein-coupled receptor 51 (GPR51)* gene. *17A* provides an interesting link between GPRs and age-associated neurodegeneration.

Lethe, in mouse embryonic fibroblasts (MEFs), lncRNAs are found to be regulated following treatment with TNF- α , a pro-inflammatory cytokine, which is associated with inflammation, aging, age-related diseases, and cellular senescence. Among these, *Lethe* was found to be particularly important for the pro-inflammatory state of aging tissues by providing a key negative feedback loop: binding of *Lethe* to the NF- κ B subunit RelA reduce the production of inflammatory proteins.

THRIL, TNF- α was also found induced by lncRNA *THRIL* (TNF- α - and hnRNPL-related immunoregulatory lincRNA). This lncRNA interacts with the TNF- α promoter and regulates its expression in *THP1* macrophages. Together, lncRNAs *lethe* and *THRIL* are involved in inflammation in a TNF- α -dependent manner.

Lnc-IL7R, was identified as a regulator of the lipopolysaccharide (LPS)-induced inflammatory response. Depletion of *Lnc-IL7R* reduces trimethylation of histone H3 at lysine 27 (H3K27me3) causing a reduction in the levels of inflammatory mediators including E-selectin, VCAM-1, IL-6 and IL-8.

The TGF- β /Smad3 pathway is involved in the inflammatory response. It has been identified that Smad3 associated lncRNAs are related to renal inflammation. The analysis identified several lncRNAs altered in Smad3 knockout mice. As this pathway is impaired with age and Smad3 regulates senescence phenotype, this network of proteins and lncRNAs differentially expressed may play a role in aging related inflammation ('inflammaging').

1.3.2. Micro RNAs

MicroRNAs are small, single-stranded ncRNAs and function to repress gene expression and influence virtually all organ systems in vertebrates. As an epigenetic regulatory mechanism, miRNAs, enable increased human complexity despite a genome size that is similar to less complex organisms. This appears to include critical roles in establishing proper inflammatory set points and facilitating optimal responses and resolution by our immune system.

Recent studies demonstrated that aberrantly expressed miRNAs exert a significant role in inflammatory genes. RNA interference mechanism culminates with the up or down regulation of hundreds of immune response genes, an essential first step in coordinating inflammatory responses. miRNAs act as a modulator of inflammation signals or as mediators between inflammation and cancer. The experimental data indicated that miRNAs have been shown to be expressed in immune cells, to target proteins involved in inflammation regulation, and consequently to affect the severity of the response. There are two major ways for the regulations: To impacting the development of inflammatory cell subsets (e.g., Th2 versus Th17) or to establish the level of immune cell function (e.g., controlling how much cytokine is made by DCs).

Certain fundamental attributes of miRNAs make them ideally suited to regulate chronic inflammatory conditions. MicroRNAs modulate immune cell differentiation and responses. Inflammation related miRNAs play important roles in various inflammatory processes. The opposing effects of miRNAs on inflammatory responses indicate that, the immune system utilizes multiple miRNAs to properly balance its functional capacity, creating a tension between activation and repression that can be precisely tuned [29]. It is still unknown how multiple miRNAs are in cooperation to balance inflammatory responses, and how miRNA networks can work together to optimize responses.

miRNAs have been implicated in regulating macrophage lineage skewing during inflammatory responses. Macrophages can be skewed toward either pro-inflammatory subtypes (M1), or less inflammatory subtypes (M2). *Mir-125* has been shown to repress M1 skewing while promoting the M2 fate. *Mir-223* has also been implicated in control of granulocyte activation, and *mir-223*^{-/-} mice display overactive immune responses and develop inflammatory lung pathology. Age dependent inflammatory phenotypes are being explored among miRNAs. It has been discovered that mice lacking *mir-146a* develop an age-dependent, chronic inflammatory disease that is spontaneous, life shortening, associated with inflammatory cytokines and autoantibodies, and that involves a variety of hematopoietic abnormalities and malignancies associated with the aging [30].

Details of epigenetic mechanisms, which play driver roles in inflammation and related diseases, will be discussed as below.

2. EPIGENETICS AND INFLAMMATORY DISORDERS

Epigenetic modifications in inflammatory autoimmune diseases have been recognized and attracted recently. Although there are many components (such as genomic variations and environmental factors), which lead predisposition of autoimmunity and related phenotypes, there are several reported epigenetic alterations as well.

The inflammatory response is a double-edged sword; immune responses are necessary for immune defense, wound repair and tissue homeostasis, if these responses become deregulated, they initiate a chronic reaction leading to chronic status. This condition, referred as *chronic low-grade inflammation*, and adversely contributes to many diseases such as aging, obesity, type 1 diabetes (T1D), rheumatoid arthritis (RA), systemic lupus erythematosus (SLE), neurodegeneration, and cardiovascular diseases (CVD) [13].

Epigenetic alterations contribute immune response and those alterations related autoimmune diseases are summarized in Table 1. In the last decade, epigenetic studies provide new insights into autoimmune diseases. The identification of specific epigenetic markers may lead to lighten uncharacterized mechanisms. Identification of clinical significance of the epigenetic markers may be utilized for diagnostic biomarkers and therapeutic benefits for the autoimmune disorders. In this section we will give some examples to the epigenetic regulations, malfunctions and markers of known inflammatory disorders;

Figure 1. Inflammation mediated diseases.

2.1. Inflammatory Bowel Disease (IBD)

Inflammatory bowel disease (IBD) is a group of inflammatory conditions of the colon and small intestine. IBD is classified as an autoimmune disease, and Crohn's disease (CD) and ulcerative colitis (UC) is the main types of the IBD. Deregulated immunologic response causes IBD and subsequently long lasting active IBD evokes to development of colorectal carcinoma in many cases. So far the data supports the notion that epigenetic factors can act as fine-tuners

of gene expression in diseases such as in IBD. Particular combinations of epigenetic changes could result in a pathogenic phenotype through activating genes that promote chronic inflammation or inhibiting anti-inflammatory gene expression in IBD. Regarding the interaction between environmental, genetic and epigenetic mechanisms seem to have great importance in the IBD. Intestinal micro biota are likely the most important environmental factor in IBD as targets of the inflammatory response [31]. It is a challenge to measure the impact of the environmental factors that potentially can contribute to IBD; thus far epigenetic factors can mediate gene-environment interactions involved in pathogenesis.

Intestinal bacteria can regulate the epithelial gene expression and the immune response by epigenetic mechanisms. Bacterial and host epigenetics can also affect host genetics to trigger inflammatory processes. A number of studies have similarly reported the bacteria induce histone modifications (see in part 2.6), thereby inflammatory response modulation and other cellular processes of the epithelium in the gastrointestinal tract [32].

The first evidence of DNA methylation, as an epigenetic mechanism in UC was reported in 1996 and found that incorporation of the 3^H -methyl groups into DNA was 10-fold higher in UC patients than controls and significantly higher in histologically active than inactive disease. A progressive increase in methylation status was found associated with neoplastic progression in UC [33]. Another reported promoter methylation on the *E-CADHERIN* gene, which is coding a specific calcium ion-dependent cell adhesion protein, was detected in 93% of dysplastic samples from UC. The result was confirmed by *E-cadherin* synthesis levels, found reduced in samples with dysplasia and normal in samples without dysplasia, suggesting that long standing inflammation is related to hypermethylation of the gene promoter and that DNA methylation may be used as a biomarker for detecting high risk patients for developing colorectal cancer [34].

Both targeted gene methylation and methylome array based studies have detected numerous colonic mucosal associates of inflammation in IBD [35, 36]. Several studies confirmed that *ER*, *MYOD*, *GSPG2* and *p16* genes were found hyper methylated in dysplastic than normal epithelium. Severe disease phenotypes of UC was found related to *MDR1* hypermethylation [37]. A tumor suppressor gene death-associated protein kinase (*DAPK*) hypermethylation was also found to be associated to the inflammation of mucosa in UC patients and a correlation is observed between higher methylation and severe inflammation [38]. DNA methylation has been found to be related to many different clinical aspects, such as disease severity, disease duration, disease phenotype, disease extent, steroid use, steroid dependence or refractoriness, age of onset, number of hospitalizations and finally active inflammation and dysplasia [39, 40].

There is limited data on concerning the contribution of DNA methylation status in CD pathogenesis. Lin et al. compared normal to inflamed tissue from CD and UC patients and found significant differences in DNA methylation of several CpG loci such as *SERPINA5*, *TNFRSF1A*, *AATK*, *GABRA5*, *MAPK10* and *STAT5A* [35]. One of the first genome wide methylation studies analyzed the methylation profiles of peripheral blood samples from women and children with CD. Several genes identified differentially methylated in patients with IBD and controls. Ontology analysis highlighted several pathways associated with IBD, including immune system processes, immune response, and host response to bacteria, whereas canonical pathway analysis indicated the involvement of Th17 cell pathways [41].

Histone modifications are complex processes and less extensively studied in IBD than DNA methylation. The patterns of histone acetylation in the colon of rats with colitis and humans with CD have been described and increased acetylation of H4 (at lysine residues 8 and 12) was determined in the inflamed mucosa and in Peyer's patches [42]. A gene-specific pattern of histone modification is observed for collagen type I, the most abundant component of the fibrotic extracellular matrix, can be induced by fibrosis relevant cytokines (IL1b, transforming growth factor beta, and tumor necrosis factor alpha) suggesting that epigenetic factors regulate fibrotic gene transcription relevant to IBD with a fibrostenosing phenotype [32]. Several anti-inflammatory mechanisms of HDACi have been proposed, one of these is T-regulatory cells, which mediate immune tolerance and repress the excessive inflammation, is linked to FOXP3 gene expression. Administration of HDACi to increased T-regulatory cell differentiation and suppression of bowel inflammation, as a result of acetylation of lysines in the Foxp3 [43]. Another mechanism could involve their effects on acetylation of proteins in the NF- κ B pathway [44].

Studies in animal models have shown that intestinal miRNAs regulate gut homeostasis [45]. Studies reported miRNA expression profiles in the peripheral blood and gut biopsy specimens of healthy controls versus adult/pediatric patients with active and inactive IBD. The miRNA expression profiles found deregulated at both the tissue level and in peripheral blood of UC and CD patients. Moreover IBD-related glucocorticoid therapy can modify the expression profile of different miRNAs [46, 47]. Specific miRNA profiles and identification of their targets might provide additional insight into IBD pathogenesis and help to predict IBD susceptibility, progression, relapse, and response to therapy. The miRNAs associated with IBD could also serve also as fine tuners of gene expression. The levels of specific mRNAs shown to be tightly controlled by miRNAs, alterations of the threshold mRNA levels results in marked changes in protein synthesis. Deregulation of the intestinal inflammatory response that results from the disruption in the balance between miRNA activity and its specific target mRNAs, e.g., genes with important functions in intestinal homeostasis [48].

Changes in miRNAs in human IBD were first described in in sigmoid biopsy specimens from patients with active UC. *MiR-192*, which is expressed in colonic epithelial cells, was found significantly reduced in tissues of patients with active UC. *MiR-192* levels were found increased in colon tissues of patients with UC leading to the expression of *macrophage inhibitory peptide 2a*, a CXC chemokine expressed in the epithelial cells [49]. *MiR-150* is up regulated in mice with dextran sulfate sodium induced colitis in colon tissues from patients with UC; its levels correlate inversely with those of its target c-Myb, which has a role in apoptosis [50]. Another miRNA, *miR-21*, which promotes inflammation, has been reported in several studies of patients with active UC and CD colitis, along with *miR-155* [51]. *MiR-196* is overexpressed in the inflamed epithelium of patients with CD [52]. Several micro RNAs have been found to be significantly up-regulated or down-regulated in 2 or more studies, including *miRs-16*, *miR-28*, *miR-149*, *miR-151*, *miR-199*, and *miR-534* in UC and CD [53]. There are several other miRNAs found related to intestinal fibrosis; *miR-29*, *miR-200b*, *miR-21*, *miR-192* or associated with epithelial barrier and immune function in IBD pathogenesis; *miR-192*, *miR-21*, *miR-126*, *miR-155*, *miR-106a* [48].

The importance of epigenetic factors in IBD derives from the mechanisms of action of some therapeutics used for the treatment of IBD. There is increasing evidence that glucocorticoids change the chromatin structure of genes that code mediators of inflammation.

Glucocorticoids can increase transcription of anti-inflammatory genes which results from the uncoiling of DNA wound around histone by acetylation of the histone residues. Glucocorticoids may also lead to deacetylation of histones on the genes of pro-inflammatory cytokines, resulting in tighter coiling of DNA and reduced access of transcription factors to their binding sites, and suppressing the target gene expression [54].

2.2. Rheumatoid Arthritis (RA)

Another chronic auto inflammatory disease, rheumatoid arthritis (RA), is characterized by synovial hyperplasia, chronic inflammation and progressive destruction of the synovial joints. RA has an unknown etiology and affecting about 1% of the population [55]. There are two subsets of RA, according to the existence of the antibody against citrullinated peptide antigens (ACPA). The presence or absence of ACPA is one of the best clinical predictors for disease outcome. The most important genetic risk factors, accounting for up to 50% of the overall risk for RA, are mainly confined to the human leukocyte antigen locus [56]. All kinds of epigenetic alterations occur in RA including DNA methylation, histone acetylation, and miRNAs has contribution [57] and continuation of the disease [58, 59].

The RA synovial fibroblasts (RASFs) play a major role in the initiation and continuation of the disease [58, 59]. These cells display an activated, aggressive and invasive phenotype [60, 61]. A global hypomethylation of the genes on these cells could be responsible for the overexpression of inflammatory cytokines in synovial fluid leading to disease phenotype [62] and these epigenetic biomarkers might provide the missing link between RA, risk factors and a lack of therapy response. Global DNA hypomethylation has also been observed in T cells and peripheral blood mononuclear cells (PBMCs) from RA patients [63].

L1 is one of the major classes of repetitive elements in the genome. Since they are methylated in the normal synovial tissue they used as biomarkers. In synovial tissue from patients with RA, L1 is hypomethylated as a consequence of reduced expression of *DNMTs*. This reduction of methylation in inflammatory response promoter genes causes an overexpression of growth factors and receptors, adhesion molecules, and cytokines, and cause irreversible phenotypic changes in synovial fibroblasts. The other hypomethylated gene, *IL-6*, is a proinflammatory cytokine that participates in B cell response. When it is hypomethylated, an overexpression of *IL-6* will occur and trigger the overexpression of pro-inflammatory cytokines at the same time and this is associated with a local hyper activation of the inflammation circuit [64, 65]. Another hypomethylated gene, *IL-1* is associated with elevated *IL-10* expression in RA and by regulating *IL-10* transcription it can be responsible for the pathogenesis of RA. Not only global but also single gene hypomethylations, such as *chemokine ligand 12 (CXCL-12)* in RASFs and (*Interleukin 1 receptor, type II*) *IL1R2*, has also been reported in RA [66, 67]. Genome-wide evaluation revealed many hypomethylated loci in RASFs including *CHI3L1*, *CASP1*, *STAT3*, *MAP3K5*, *MEFV*, and *WISP3* [12].

Besides hypomethylation, CpG hypermethylations in the regulatory regions of some genes lead to aberrant transcription in RA. Hypermethylation of *EBF3* and *IRX1* genes interacts with transforming growth factor beta (TGF- β) pathway components and reduce mRNA expression in RASFs [68]. The promoter region of the *death receptor 3 gene (DR3)*, a member of the apoptosis inducing FAS family, was shown to have significant hypermethylation of CpG

islands in RA patients, which may enhance resistance to apoptosis in RA synovial fibroblasts [57, 69].

The gender bias (3:1/F:M) of RA suggests an X-chromosome role in the development of RA. An increased presence of a skewed X-chromosome inactivation pattern has been shown in the peripheral blood of a RA patient. Instead of a random X-chromosome inactivation, 80% or more of the cells exhibited inactivation of the same X-chromosome. CD40 ligand (CD40L) is primarily expressed at the surface of activated CD4⁺ T helper cells and plays a crucial role in the immune response. A promoter hypomethylation and increased expression of CD40L has been detected in CD4⁺ T helper cells of female RA patients. Hypomethylation of genes on the inactive X chromosome may contribute to female-biased RA patients [70, 71]. The exposure to *IL-1* decreases the mRNA levels of *DNMT1* and *DNMT3a* in RASFs and also inhibits global methylation of RA fibroblast-like synoviocytes (FLS), suggesting the contribution to differential DNA methylation in RASFs through altered expression of *DNMTs*.

RA synovial tissue is characterized by an imbalance between HAT and HDAC activity. Cartilage destruction that is mediated by matrix metalloproteinases (MMPs) and enzymes from the ADAMTS family, are regulated by chromatin modifications and histone acetylations. HDAC inhibitors inhibit cartilage degradation by blocking the induction of certain MMPs by proinflammatory cytokines. Hyper acetylation of synovial cell histones, induce cyclin dependent kinase inhibitors (p16 and p21) expression via decreased *tumor necrosis factor-alpha* (*TNF-α*) expression (72, 73). Additionally the hyper acetylation of histones down regulate HIF-1α (hypoxia inducible factor) and vascular endothelial growth factor (VEGF) to block angiogenesis in synovial cells [74].

DNA methylation has been shown to regulate the microRNAs (miRNAs) expressions in RA. Demethylation with 5-azacytidine (5-azaC) increases the expression of *miR-203* in RA [75]. The increased levels of *miR-203* result in elevated secretion of MMP-1 and IL-6 via the NF-κB pathway, and thereby, contribute to the activated phenotype of RASFs. MeCP2 is a chromatin-binding protein that preferentially binds to methylated CpGs and is highly abundant in the synovium of RA rats. It has also been shown that increasing global methylation levels are regulated by overexpression of *MeCP2* in a RA rat model [76]. The promoter of *miR-124a* hypermethylation implicated in the proliferation of FLS [77]. The recent genome-wide methylation studies have reported hypomethylation and hypermethylation of multiple genes in tissue-derived FLS from patients with RA [78-82].

Micro RNAs have also been implicated in RA [63]. Primary human samples have increased expression of *miR-155*, *miR-146*, and *miR-223* and mouse arthritis models have demonstrated the functional relevance of *miR-155* and *miR-182* for regulating B and T cell function during disease [83-86]. *MiR-146* and *miR-155*, are shown to be induced by proinflammatory stimuli such as *IL-1*, *TNFα*, and *Toll-like receptors (TLRs)*. Another miRNA implicated in RA is *miR-124*, which targets *cyclin-dependent kinase 2 (CDK-2)*. In the basal state, *CDK2* represses cell proliferation and arrests the cell cycle at the G1 phase, but in pathologic conditions such as RA, its level decreases. *MiR-124* also targets *monocyte chemo attractant protein 1 (MCP-1)*, which is responsible for mononuclear phagocytes into the joint. Thus this miRNA increases cell proliferation and MCP-1 production in RA [87]. *MiR-203* is overexpressed in RASF, enhancing the secretion of MMP-1 and interleukin-6 [75]. Tumor necrosis factor-α induces *microRNA-18a* and activates RASF through a feedback loop in NF-κB signaling [88].

2.3. Systemic Lupus Erythematosus (SLE)

Systemic Lupus Erythematosus (SLE) is a systemic autoimmune disease with multiple organ involvement, which is characterized by autoantibody response to nuclear or cytoplasmic antigens. It is defined with the production of increased amount of autoantibodies, which potentially drive immune complex related inflammation in various tissues and organs [89]. Several genetic and epigenetic factors contribute to the development of SLE. Epigenetic disruption results in overexpression of certain genes of the key immune cells, such as T cells, has been associated with the pathophysiology of SLE. Self-antigens resulting in inflammation mediated multiple organ damage, displays global H3 and H4 hypoacetylation in the CD4⁺ T cells of patients [90, 91].

Like RA, SLE is more common in females with peak disease prevalence between menarche and menopause. Estrogen increases the risk of SLE in women via increasing the type 1 interferon (IFN) production and survival of auto reactive B-lymphocytes [92, 93]. Epigenetic modifications might explain the female prevalence for SLE. Impaired DNA methylation presented on the inactive X-chromosomes of SLE patients was suggested to contribute to the female predominance of SLE [94].

The roles of DNA methylation in SLE first described in the 1960s and since then it become a very hot research topic [95]. Several studies have shown that there is a global hypomethylation of promoter regions, which contain the genes that are overexpressed in the SLE like *ITGAL*, *CD40LG*, *PRF1*, *CD70*, *IFGMR2*, *MMP14*, *LCN2*, and in the ribosomal RNA gene promoter (18S and 28S) [94, 96, 97]. The DNA hypomethylation may also affect the chromatin structure of T-cells and leads the overexpression of these genes. The genes overexpression will cause cell hyperactivity and perpetuation of inflammatory response [98]. Genome-wide methylation studies have provided new insights into the role of DNA methylation in the pathogenesis of SLE. The regulatory regions for interferon-responsive genes in naive CD4⁺ T cells from patients with SLE are hypomethylated and ‘poised’ for expression; transcription does not occur until T-cell activation [99].

Histone modifications in SLE have been studied in animal models and in human diseases. These studies showed that, during apoptosis, histones could be modified to make them immunogenic. The antibodies are directed against components of the cell nucleus that are exposed at the cell surface during apoptosis [100, 101]. The nucleosomes, the primary pioneer antigen in SLE, are released in patients with SLE as a result of a corrupted apoptosis or an insufficient clearance of apoptotic residue. During apoptosis, the nucleosome is modified and creates more immunogenic epitopes leading to the formation of autoantibodies against unmodified chromatin components [102]. Histone modifications such as histone 3 lysine 4 trimethylation (H3K4me3), histone 3 lysine 8 (H4K8ac) triacetylation, histone 3 lysine 27 trimethylation (H3K27me3), and histone 2B lysine 12 acetylation (H2BK12ac) cause an increase in apoptotic nucleosomes. These apoptotic nucleosomes generate auto-immunogenicity that can cause activation of antigen presenting cells and autoantibody production with a subsequent inflammatory response [103]. There are other studies that have shown acetylation patterns of histone H3 and H4 in active SLE CD4⁺ T cells [104]. Monocytes, which are important in SLE renal disease, have been shown to have an altered acetylation pattern of histone H4 thus increasing the expression of interferon (IFN) genes that play a key role in SLE pathogenesis [89, 105].

Epigenetic reprogramming has potential preventive and therapeutic purposes for inflammation and autoimmunity. Two methylation inhibitors, procainamide and hydralazine, were found to induce a lupus-like disease after long-term administration in wild-type mice, and the disease disappeared after the withdrawal of these drugs. DNA demethylation has been found in SLE CD4⁺ T cells, but not in CD8⁺ T cells or peripheral blood mononuclear cells (PBMCs) [106]. The recent researches have focused on specific cell types as well as certain SLE relevant genes. Among the other inhibitors procainamide, is a competitive inhibitor of DNMT1 and hydralazine inhibits T and B cell signal regulated kinase pathways that play an important role in the regulation of methylation [107, 108]. These two therapeutic mechanisms produce a reduction in DNMTs that will enhance the genetic expression of adhesion molecules on lupus-drug-induced lymphocytes [109].

Several studies suggest a role for miRNAs in the pathogenesis of SLE. MicroRNAs control the differentiation and function of B cells, which are considered key elements in the pathogenesis of systemic lupus erythematosus (SLE) [110]. For example the under expression of miR-1246 through the AKT-P53 signaling pathway, leads to the expression of *EBF1*, and promote the activation of B cells [111].

Peripheral blood mononuclear cells from patients with SLE showed differential expressions in some miRNAs (increased *miR-189*, *miR-61*, *miR-78*, *miR-21*, *miR-142-3p*, *miR-342*, *miR-299-3p*, *miR-198*, and *miR-298* and decreased *miR-196a*, *miR-17-5p*, *miR-409-3p*, *miR-141*, *miR-383*, *miR-112*, and *miR-184*) [112]. The expression of *miR-21* which targets an important autoimmune gene *RASGRP1*, is increased in CD4⁺ T cell of SLE patients and mediates the RAS–MAPK pathway, down regulating *DNMT1* expression [113]. Similarly, increased levels of *miR-21* found contributed to the B cell hyper responsiveness and aberrant T cell response in SLE by targeting the *PTEN* and *PDCD4* respectively [114-116]. Besides *miR-21*, *miR-126* was also reported to modulate DNA methylation in SLE CD4⁺ T-cells by directly targeting DNMT1 [106].

MiR-146a is a well-recognized negative regulator in autoimmunity. *MiR-146a* was found under expressed in SLE [117] and this was possibly due to a germline genetic variant in the *miR-146a* promoter [118]. This genetic variant (rs57095329) in the promoter region of *miR-146a* confers association with its expression level. The SLE risk-associated G allele of the variant is linked to a reduced *miR-146a* expression in PBMCs, possibly by affecting the protein binding affinity and activity of the promoter. A reverse correlation of *miR-146a* levels with the expression of interferon inducible genes and SLE disease activity was reported, indicating a critical role of *miR-146a* in excessive type I interferon production and signaling activity in SLE [117]. *MiR-146a* has been shown to negatively modulate type-I IFN production in macrophages through targeting TLR signaling genes *TRAF6*, *IRAK1* and *IRAK2* [119]. *MiR-146a* is often bundled with TLR7/9 stimulation, which plays a central role in SLE pathogenesis. Apart from PBMCs, TLR7/9 stimulation in plasmacytoid dendritic cells (pDCs) also induces *miR-146a* expression [120].

SLE patients have multiple clinical features caused by inflammation. *MiR-23b* was found under expressed in the affected tissues of patients with SLE. It has been reported that *miR-23b* targets *TAB2*, *TAB3* and *IKK- α* to inhibit *IL17*, *TNF* or *IL1 β* signaling [121]. Many miRNAs contribute to the reduced IL-2 production in lupus patients. A significant reduction in *miR-31* expression in SLE T cells is positively correlated with the lowered IL-2 production [122].

2.4. Multiple Sclerosis (MS)

Multiple Sclerosis (MS) is another disease characterized by myelin destruction followed by a progressive degree of neurodegeneration. Inflammation is an important mechanism of CNS damage in MS, and proper transcriptional control of the immune responses is mediated in part by epigenetic regulation.

Peptidyl arginine deiminase type II (PADI2) has been found hypomethylated in MS patients [123]. *PADI2* plays a key role in the citrullination process of myelin basic protein (MBP) that promotes protein auto cleavage and increases the probability of creating new epitopes and also modulates the immune response. In MS, an increase has been found in demethylase enzyme activity, which will cause hypomethylation of the *PADI2* promoter region [123, 124]. Hypomethylation increases *PADI2* expression and MBP citrullination process via the production of immunodominant peptides, which will increase the autocleavage of MBP, causing irreversible changes in its biological properties, and will produce proteolytic digestion, myelin instability, and a chronic inflammation response [125]. *SHP-1* gene is the negative regulator of pro-inflammatory signals. Increased promoter methylation in leukocytes in more than one-third of the MS subjects leading to decreased *SHP-1* expression and increased leukocyte-mediated inflammation [126]. CD4⁺ T-cells of relapsing-remitting multiple sclerosis patients showed *FOXP3* and *IL-17A* demethylation. *FOXP3* demethylation inhibits Th1 and Th2 cell differentiation and promotes Th17 cell lineage commitment, whereas the *IL-17A* leads to increased differentiation towards the Th17 cell lineage. Epigenetic control of the Th1/Th2/Th17 balance through to determine disease status [127, 128]. Genome-wide methylome analysis confirmed a global DNA hypermethylation of CD8⁺ T cells for MS patients [129].

The oligodendrocyte identity is modulated by posttranslational modifications of histones. In patients with MS, there is a shift toward histone acetylation in the white matter. Hyperacetylation of H3 in the promoter region of inhibitory genes produce high levels of transcriptional inhibitors of oligodendrocyte differentiation such as *TCF7L2*, *ID2*, and *SOX2* [130]. H3 hyperacetylation is accompanied by an increase in number and activation state of microglia and astrocytes. While the expression of histone deacetylases showed *HDAC8* and *HDAC11* up-regulation, only a subgroup of patients showed overexpression of a number of genes including *TCF7L2*, *SOX2* and *IDS* [131].

Many studies have focused on miRNA involvement in MS pathogenesis. Among those, the *miR-326* plays a critical role in the pathogenesis of MS via upregulation of the Th-17 cell differentiation by targeting Ets-1, which acts as a negative regulator of Th-17 differentiation. *MiR-326* was found significantly upregulated in patients with relapsing-remitting MS, which produced more severe symptoms [132]. Other miRNAs involved in MS are *miR-34a* and *miR-155*, are also upregulated in active MS lesions and contribute to MS pathogenesis by targeting CD47, which is a “don’t eat me” signal Macrophages with low levels of CD47 are released via inhibitory control signals, leads to increased phagocytosis of myelin. *miR-155* also promotes development of inflammatory Th1 and Th17 cells [133].

Differentially expressed *miR-17-5p*, *miR-497*, *miR-193*, and *miR-126* have been identified in different lymphocyte subsets including CD4⁺ T cells, CD8⁺ T cells, B cells, and CD4⁺ CD25⁺ Treg cells from patients with MS. Direct involvement and contribution of deregulated miRNAs in MS still needs additional investigation [133, 134]. It is noteworthy that all miRNAs are involved in the pathogenesis of the disease. There are miRNAs that can serve as prognostic

markers such as the expression of *miR-18b* and *miR-599* is related to relapse and *miR-96* is involved in remission [135]. *MiR-124*, which is expressed in microglia, is brain specific and it might reduce the activation of myelin-specific T cells with a marked suppression of the disease, which would make it a key regulator of microglia quiescence and a good prognostic factor for MS [136].

2.5. Diabetes

The environmental factors and nutrition play an important role in the pathogenesis of diabetes. However, the knowledge on molecular mechanisms by which these factors trigger β -cell dysfunction and diabetes are still limited. Recent discoveries give an impression that epigenetic changes in response to environmental stimuli may play an important role in the development of diabetes. Chronic exposure to high concentrations of glucose, leading to oxidative stress and inflammation, may induce changes in the regulation of gene expression on insulin secretion and increased apoptosis. The combination of inflammation, mitochondrial dysfunction and ROS production provides an attractive model for the pathogenesis of diabetes and may explain the widespread alterations of epigenetic regulation of gene expression during the glycemic control [137, 138].

Type 1 Diabetes (T1D) is a T-cell-mediated autoimmune disease that develops in genetically susceptible individuals and affects their endocrine pancreas. There are some mechanisms by which epigenetics may play an important role in T1D by modulating lymphocyte maturation, cytokine gene expression and by differentiation of subtype Th cells ruled by epigenetic controls. In this autoimmune disease, in contrast to SLE and RA, there is a global hypermethylation activity caused by altered metabolism of homocysteine [139]. Glucose and insulin levels are determinants of methylation, they alter homocysteine metabolism by increasing cell homocysteine production [140, 141]. When there is an increase in the levels of homocysteine, methionine in cells will be catalyzed by DNMTs in S-adenosylmethionin, which will enhance DNMT activity, and lead to increased global DNA methylation. Elevation of maternal homocysteine during pregnancy as a result of a low protein diet can produce an altered methionine metabolism that will cause a decrease in islet mass and vascularity in the fetus with a subsequent glucose intolerance in adult life [142]. The reduced *Foxp3* expression was found to be associated with *Foxp3* promoter hypermethylation in adult autoimmune diabetes patients [143].

There are limited studies associated with histone modifications and T1D. Patients with T1D show a subset of genes with an increase in histone 3 lysine 9 dimethylation (H3K9me2) in lymphocytes. This subset of genes includes the *CLTA4*, which is a T1D susceptibility gene and has increased methylation of H3K9 in its promoter region. Other genes that have altered H3K9me2 are *transforming growth factor-beta (TGF- β)*, *NF- κ B*, *p38 (mitogen-activated protein kinase)*, *toll-like receptors (TLRs)*, and *IL-6*. The transcription factor *NF- κ B* is also upregulated by H3K4 methyltransferase thus causing an increase in inflammatory gene expression in diabetic mice. All these genes are associated with autoimmune and inflammation related pathways [144, 145]. Histone modifications are also among the mechanisms that cause cardiovascular complications in T1D patients. Chemical modification of H3K4 and H3K9 has been found to be related to the gene expression conferred by hyperglycemia. Transient hyperglycemia promotes gene activating epigenetic changes and signaling events critical in the

development and progression of vascular complications. These epigenetic changes are H3K4 and H3K9 methylation in genes associated with vascular inflammation [146, 147].

There are some hypotheses that the function of regulatory T cells (Tregs) is influenced by changes in the expression of specific miRNAs in T1D. *MiR-510* expression was found to be increased and *miR-342* and *miR-191* expressions were found to be decreased in Tregs of diabetic patients. There are other studies, which demonstrate that miRNAs may be the cause of cytokine mediated beta-cell cytotoxicity. This cytotoxicity is achieved when IL-1B and TNF- α induce the expression of *miR-21*, *miR-34a*, and *miR-146a* in pancreatic islets thus producing beta-cell failure by increasing proinflammatory cytokines [148]. *MiR-101a* and *miR-30b* are key players and contribute to cytokine-mediated β -cell dysfunction in the development and progression of type 1 diabetes. IL-1 β induces *miR-101a* and *miR-30b* expression and participates in β -cell dysfunction, including decreased insulin content, gene expression, and increased β -cell death. *MiR-101a* and *miR-30b* reduce pro-insulin expression and insulin content by directly targeting the transcriptional factor Neurod1. In addition, these miRNAs associated with diminished expression level of the antiapoptotic protein Bcl2 [149]. A significant increase of *miR-21* has been observed in the plasma and urine of pediatric T1D. In a type 1 diabetes mouse model, high glucose induced *miR-21* de-repress TORC1-pathway and leads to renal pathologies [150]. In a type 2 diabetes model *miR-21* down regulates phosphorylated SMAD-7, leading to up-regulation of TGF- β and nuclear factor- β signaling pathways, increasing renal fibrosis and inflammation [151].

2.6. Bacterial Infections

Recent studies revealed that bacteria could affect the chromatin structure and transcriptional program of host cells by influencing diverse epigenetic events (i.e., histone modifications, DNA methylation, chromatin-associated complexes, noncoding RNAs, and RNA splicing factors). Bacterial-induced epigenetic deregulations may affect host cell function either to promote host defense or to allow pathogen persistence. Their effects might generate specific, long-lasting imprints on host cells, leading to a memory of infection that influences immunity. The selective activation or silencing of specific genes not only depends on transcription factors, but also on their cross talk with epigenetic modulators, which regulate DNA accessibility by controlling the chromatin structure.

The importance of DNA methylation events associated with bacterial infections is attracting attention. The best documented example is *H. pylori* infection leading aberrant DNA methylation in the human gastric mucosa, strikingly at promoters of genes found to be methylated in gastric cancer cells [152]. *H. pylori* associated hypermethylation is seen at the *CDH1*, *USF1*, *USF2*, *WWOX*, *MLH1* genes [153]. *H. pylori* mediated inflammation triggered lymphocyte and macrophage infiltration, which appears to have a key role in induction of methylation [154]. Among signals resulting from chronic inflammation, elevated levels of interleukine 1b (IL1b) and nitric oxide (NO) are proposed to contribute to influence the recruitment of DNMTs.

In the intestine, following chronic inflammation, some *PRC2* target genes are subject to aberrant DNA methylation [155]. Bacteria-induced DNA methylation can also affect genes involved in cell proliferation. In human uroepithelial cells, infection with uropathogenic *Escherichia coli* (UPEC) results in the up regulation of DNA methyltransferase (DNMT)

activity and DNMT1 expression, and induces CpG methylation and down-regulation of *CDKN2A*, a G1-cell-cycle inhibitor regulator [156]. This may increase uroepithelial cell proliferation and pathogen persistence, by infection stimulated host cell apoptosis.

Other organs can also be targeted by bacteria-mediated epigenetic changes, including placenta. Maternal infection with *Campylobacter rectus* induces hypermethylation of the imprinted *IGF2* gene promoter in murine placental tissue [157] suggesting that bacterial infections during pregnancy might epigenetically affect genes that play an important role in fetal development.

Mechanisms controlling gene expression at the chromatin level show high levels of complexity. Various bacterial products can affect them in many ways, through activation of signaling cascades or directly in the nucleus. The most of the reported chromatin modifications induced by bacteria are histone modification (acetylation/[deacetylation and phosphorylation/dephosphorylation) events generated through activation of host cell signaling cascades. Among the host signaling pathways that certain bacteria activate, MAPKs, NF- κ B, and PI3K pathways are known to activate the kinases. *B. vulgatus* induces TGF- β anti inflammatory pathway, and H3 de-acetylation via HDAC recruitment at proinflammatory gene promoters [158]. Bacterial toxins also dampen the host innate immune responses by inhibiting H3 phosphorylation/acetylation. The lethal toxin (LT) from *Bacillus anthracis*, the agent of anthrax, cleaves and inactivates MAPKKs leading to disruption in MAPK signaling [159].

H. pylori is also capable of modifying histones via the modulation of the MAPK pathway. The peptidyl prolyl cis, trans isomerase HP0175 secreted by *H. pylori* binds the innate immunity receptor TLR4 and activates MAPKs in monocytes [160]. Another study showed that exposure of *H. pylori* to gastric epithelial cells promotes release of HDAC1 from the promoter of the cell-cycle regulator gene *p21^{WAF}*, hyperacetylation of H4, and increased expression of *p21^{WAF}*. Chromatin alterations might contribute to the effects of *H. pylori* on cell cycle progression, cellular proliferation, and cell death [161].

Pore-forming toxins use another signaling pathway to change histone marks. He-La cells, *L. monocytogenes* listeriolysin O (LLO) promotes histone deacetylation and dephosphorylation in a subset of immune genes such as *CXCL2*, *MKP2* and *IFIT3* which cause repression [162]. Other pore-forming toxins, such as PFO of *Clostridium perfringens*, PLY of *Streptococcus pneumoniae*, and Aerolysin from *Aeromonas hydrophila* have similar effects, leading to histone modification [163].

Bacteria can also produce metabolites acting as inhibitors of chromatin-modifying enzymes. One such product is butyric acid, a short-chain fatty acid acting as a potent inhibitor of HDACs [164]. The adverse effect of *Porphyromonas gingivalis* in reactivating latent viruses, such as human immunodeficiency virus (HIV) and Epstein – Barr syndrome (EBV), result from production of butyrate by this bacterium [165]. It is proposed that viral genes maintained silent by HDAC-containing complexes are reactivated following inhibition of HDACs by butyric acid. Butyric acid also exerts anti-inflammatory effects on the host, via epigenetic up-regulation of anti-inflammatory genes. These observations give the idea of the usage of butyrate-producing probiotic bacteria as immunosuppressors [166].

miRNAs are important regulators of immune responses that are induced in response to pathogenic bacteria, such as *H. pylori*, *Salmonella typhimurium*, *L. monocytogenes*, and *Mycobacterium bovis* BCG [167, 168]. Whether a bacterial stimulus induces expression of miRNA or endogenous siRNA acts at the chromatin level in the nucleus is unknown. *MiR-155*, *miR-146*, *miR-125*, *let-7* and *miR-21* which are involved in immune responses and protection

against harmful effects of inflammation, play important roles in the response of host cells to bacteria [169]. These miRNAs are involved in immune responses as well as in the protection against harmful effects of inflammation. miRNAs are involved in the regulation of proliferation, differentiation and apoptosis pathways induced by pathogenic bacteria in their host cells. A role for miRNAs that control bacteria populations and their production of metabolites leading to inflammatory conditions is beginning to emerge. It has got important implications both within the gut and in peripheral tissues.

Table 1. Selected epigenetic deregulations and inflammatory conditions

DISEASE	DNA METHYLATION	HISTONE MODIFICATION	Micro RNA
IBD	<i>ER, MYOD, GSPG2, p16, CDH1, GDNF, E-CAHERIN, DAPK, MDR1, SERPINA5, TNFRSF1A, AATK, GABRA5, MAPK10, STAT5A</i> hypermethylation [34-38]	<i>COL1, FOXP3</i> [32,43]	<i>miR-125, miR-155, miR-192, miR-150, miR-21, miR-196</i> [49-52]
RA	<i>FOXP3, SFRP1, SFRP4, EBF3, IRX1, DR3</i> hypermethylation [57, 68, 69] <i>L1 repeats, IL-6, IL-1, CXCL-12 CD40LG, IL1R2, CHI3L1, CASP1, STAT3, MAP3K5, MEFV, and WISP3</i> hypomethylation [12, 64-67, 70, 71]	<i>EXH2, SITR1, ADAMTS, p16, p21, VEGF, HIF-1a</i> [72-74]	<i>miR-21, miR-30a-3p, miR-146a, miR-155, miR-223, miR-182, miR-203, miR-124a, miR-18a</i> [4, 14, 83-87]
SLE	<i>IL-10, IL-13, IFIT2, IRF5, STAT1, CD5, HRES1, IFNGR2, 18S and 28S</i> hypomethylation [93-96]	<i>IFN</i> genes [88, 102-104]	<i>Let-7a, miR-21, miR-29, miR-146, miR-182, miR-17-92, miR-155, miR-1246, miR126, miR-23b, miR-31</i> [110, 115-119, 120,121]
MS	<i>PADI2</i> -hypomethylation [122, 123] <i>FOXP3</i> and <i>IL-17A</i> hypomethylation [126] <i>SHP1</i> -hypermethylation [125] Global hypermethylation in CD4+ T cell [128]	<i>TCF7L2, ID2, IDS</i> and <i>SOX2</i> [125, 126]	<i>miR-21, miR-29b, miR-115-miR-326-, miR-124, miR34a, miR-17-5p, miR-497, miR-193, and miR-126, miR-18b, miR-599, miR-96</i> [127-131]
Diabetes	<i>FOXP3</i> - hypermethylation [142] Global hypermethylation [138]	<i>CLTA4 TGF-β, NF-κB, p38, TLRs, and IL-6. NF-κB</i> [138, 139]	<i>miR-29, miR-510 miR-146a, miR-342, miR-191, miR-21, miR-34a, miR-101a and miR-30b</i> [142-144]
Bacterial infection	<i>H. pylori</i> induced hypermethylation seen at the <i>CDH1, USF1, USF2, WWOX, MLH1</i> [147] <i>E. coli</i> (UPEC) induced hypermethylation of <i>CDKN2A</i> [150]	<i>B. vulgatus</i> induces TGF-1β pathway [152] <i>B. anthracis</i> inactivates MAPKKs [153] <i>H. pylori</i> induces cell-cycle regulator gene <i>p21</i> ^{WAF} [155]	<i>MiR-155, miR-146, miR-125, let-7 and miR-21</i> (168)

IBD; inflammatory bowel disease, RA; rheumatoid arthritis, SLE; systemic lupus erythematosus, MS; multiple sclerosis

3. EPIGENETICS, INFLAMMATION AND CANCER

Cancer has traditionally been described as a disease that is driven by the accumulation of genetic variations [170]. In addition to genetic alterations, it is well known now that epigenetic changes also play an important role in the development and progression of cancers [15, 171]. Self-sufficient proliferation, insensitivity to anti-proliferative signals, evasion of apoptosis, limitless replicative capacity, the maintenance of vascularization, invasion and metastasis are the hallmarks of cancer [170, 172]. In fact, the genetic background of cancer is relatively straightforward: mutation of tumor suppressors and/or oncogenes causes either loss or gain of function and abnormal expression. However, the epigenetic pathway to cancer is more complex and comprised by chromatin structure including DNA methylation, histone variants and modifications, nucleosome remodeling as well as small non-coding regulatory elements. During the carcinogenesis, the epigenome goes through multiple alterations, including a genome-wide loss of DNA methylation, frequent increases in promoter methylation of CpG islands, changes in nucleosome occupancy and modification profiles [173, 174]. Outcome of next generation sequencing studies has been the discovery of many inactivating mutations in genes that have potential to disrupt DNA methylation, histone modification and gene expression. The current studies have indicated that genetic and epigenetic mechanisms are not two separate states in cancer; they intertwine and take advantage of each other during tumorigenesis. Alterations in epigenetic mechanisms can lead to genetic mutations and genetic mutations in epigenetic regulators lead to an altered epigenome [174].

Inflammation is part of our natural healing process and there are two types of inflammation; chronic and acute. Acute inflammation plays a beneficial role against infection and injury. However, inadequate resolution of inflammation and uncontrolled inflammatory reactions can arouse a state of chronic inflammation and may play role in cancer development and progression [5, 175]. The link between cancer and inflammation has long been recognized. Accumulating evidence from preclinical and clinical studies suggested that persistent inflammation functions as a driving force in the journey to cancer [176]. It was estimated earlier that out of 2.2 million cancer cases diagnosed in the world on average more than 15% cases could be rooted to infection [177]. For instance, cancer of stomach, liver, gallbladder, prostate, and pancreas are usually related to gastric inflammation [176]. There is about 1.2 million new patients diagnosed with colorectal cancer and patients suffering from inflammatory bowel disorders, such as ulcerative colitis and Chron's disease, have an increased risk of developing colorectal cancer [176, 178]. Beside that management of colitis with anti-inflammatory therapy reduces this risk [179, 180].

The association between inflammation and cancer has two paradigm; inflammation cause cancer (extrinsic mechanism), cancer cells produce toxins and alert the immune system, when cancer has started, inflammation makes the tumor grow, creates a blood supply then spreads the cancer (intrinsic mechanism) [181]. Chronic hepatitis based hepatocellular carcinoma and colon cancer caused by inflammatory bowel diseases are two examples for extrinsic mechanisms [178, 182]. The intratumoral inflammatory microenvironment acts as a favorable ground for premalignant cells to attain malignant properties by allowing tumor cells to escape from host immune attack, inducing epigenetic changes, enforcing epithelial to mesenchymal transition, and providing unlimited growth potential, thereby creating a vicious cancer-

inflammation-cancer axis [176]. For instance, the mutation of RAS family proteins trigger RAS-RAF signaling and results in aggressive tumor formation [183, 184].

Several biochemical processes that altered during chronic inflammation have been implicated in carcinogenesis. These include shifting cellular redox balance toward oxidative stress, induction of genomic instability, increase DNA breakage, stimulation of cell proliferation, metastasis and angiogenesis, deregulation of cellular epigenetic control of gene expression. One of the mechanisms by which consistence inflammation can initiate tumorigenesis is the generation of oxidants and subsequent DNA damage leading to activation of oncogenes and/or silencing of tumor suppressors [185]. A wide variety of inflammatory and innate immune cells are often gathered at the site of infection. As a response to proinflammatory stimuli, activated inflammatory/immune cells generate reactive oxygen species (ROS) and reactive nitrogen species (RNS), which cause DNA damage. DNA damage can lead to activation of oncogenes [186]. Chronic exposure to ultraviolet (UV) B radiation is known to trigger inflammatory tissue damage and skin cancer through the activation of *ras* oncogene and loss of function of *p53* tumor suppressor gene [187]. NO, another reactive species, plays a role in inflammation related carcinogenesis by modification of DNA and inactivation of DNA repair enzymes [186]. 8-Oxo-7,8-dihydro-2'-deoxyguanosine (8-oxo-dG), a major biochemical hallmark of oxidative and mutagenic DNA damage, has been found to be produced in association with *H.pylori* induced gastric and TNF- α -induced pulmonary carcinogenesis. In general, inflammation driven activation of various protein kinases that include Janus-activated kinase (JAK), Akt, and mitogen-activated protein (MAP) kinases unbounded transmits growth signals, allowing cells to acquire a malignant phenotype [181, 188, 189].

Beside the mutations in the genomic DNA, epigenetic alterations can change gene expression via DNA methylation, histone modifications and non-coding regulatory elements. Traditionally, DNA methylation studies mostly have focused on CpG islands. DNA methylation, the addition of a methyl group to the 5-position of cytosine base in the DNA, represents a critical epigenetic control of gene expression [174, 190, 191]. The CpG hypermethylation of E-cadherin gene in intestinal metaplasia in *H. pylori* infected patients suggests DNA hypermethylation as a preneoplastic event in gastric cancer [192, 193]. Moreover, *H. pylori* infection has been shown to cause DNA involvement of epigenetic alterations in inflammation-associated cancers. Gene silencing via promoter hypermethylation in tumor suppressor genes *p16*, *RUNX3*, *MLH1* and *HPP1* are seen in ulcerative colitis and Barretts esophagus, which are closely associated with gastric carcinogenesis [193, 194]. Tissue specific expressed and imprinted genes can show hypomethylation, which may contribute to cancer cell phenotype. Recent genome wide methylation analyses have allowed to systematically discovering the key features of tumor methylomes. These include not just hypermethylated CpG islands, but also large (several 100 kb to several Mb) partially methylated domains that are localized at intergenic regions [195]. Another novel feature of methylomes is DNA methylation valleys (DMV) that are strongly hypomethylated in most tissues, and become hypermethylated in several cancers [196]. Abu-Remaileh et al. has shown the dynamic hypermethylation of DMVs and identify it as an early event in inflammation induced intestinal tumorigenesis. Aberrant methylation of DMVs may be novel epigenetic programs that links intestinal inflammation to colon cancer [197].

Epigenetic mechanisms may modulate the expression of pro-inflammatory cytokine TNF- α , interleukins, tumor suppressor genes, oncogenes and autocrine and paracrine activation of the transcription factor NF- κ B [3, 198]. In areas of tissue inflammation, activated neutrophils

and eosinophils release HOCl and HOBr, which react with DNA to produce 5-chlorocytosine and 5-bromocytosine, respectively [176, 199]. Neither methyl-binding proteins nor DNA methyltransferase-1 (DNMT-1) can distinguish between these inflammation-damaged 5-halocytosines and 5-methylcytosine. Thus, the formation and persistence of 5-halocytosine residues in the DNA of cells at the site of inflammation may lead to inappropriate de novo DNA methylation and represent another important link between inflammation and cancer development [176, 199]. Treatment of human multiple myeloma KAS 6/1 cells with a proinflammatory cytokine IL-6 was resulted an increased expression of *DNMT-1* and hypermethylation of the *p53* promoter. Zebularine is the DNMT inhibitor and restores the normal *p53* function by demethylating *p53* promoter [200].

On the other hand, hypomethylation of epidermal growth factor (*EGFR*) gene in IL-6-transfected malignant cholangiocytes is involved in increasing *EGFR* expression, thereby promoting growth of cholangiocarcinoma cells [201]. Moreover, silencing of cytokine signaling by epigenetic modification revealed resistance to apoptosis in cholangiocarcinoma cells via sustained inflammatory signaling mediated by IL-6/signal transducer and activators of transcription (STAT-3) and subsequent expression of myeloid cell lymphoma-1 (Mcl-1) [176, 202].

Gene expression changes can be modulated by the modification of histones and their variants. Indeed, aberrant histone modifications are already known hallmarks of different cancer types [27]. Histone related enzymes HDACs and HATs have been linked to chronic inflammatory responses and cancer [203, 204]. The acetylation of lysine residues on the N-terminus of histones by HATs activates gene transcription; on the other hand removal of an acetyl group from lysine residues in histone tails by HDACs leads to transcriptional suppression of genes. Hypermethylation itself may also lead to histone deacetylation and chromatin condensation, thereby instigating a transcriptionally silenced state [205, 206]. Transcriptional regulation of inflammatory cytokines and related pathways such as NF- κ B by proinflammatory stimuli depends on histone regulations. Therefore, the inflammation induced alterations in histones and linking upregulation of COX-2 and NF- κ B suggest that inflammation can change the cellular epigenetic machinery, thereby indirectly induce the genetic instability of cancer cells [176]. Beside intranuclear functions, histones can also be released into the extracellular space by damaged and activated cells, presenting toxic or pro-inflammatory activity *in vivo* and *in vitro* [26, 27]. When extracellular histones released, they selectively bind to Toll-like receptors to produce pro-inflammatory cytokines (TNF- α and IL-6), which in turn accelerates inflammatory response and tissue damage [207].

Several miRNAs can behave as oncogenes or tumor suppressors in cancer. Cytokine regulated miRNAs can function as a critical link between inflammation and cancer. UC patients revealed the upregulation of several miRNAs, including *miR-21* and *miR-155* according to healthy controls [208]. Upregulation of *miR-let-7a* may play a role in inflammation-associated cholangiosarcoma. Stable overexpression of IL-6 induces *miR-let-7a*, which contributes phosphorylation of STAT3 in malignant cholangiocytes [181, 209]. As an alternative way, IL-6 can enhance the growth of human cholangiocarcinoma cells by downregulating *miR-370* [210]. Therefore, the role of miRNA in inflammation and cancer mostly depends on mechanisms by which tumor cells and tumor microenvironment regulate miRNA biogenesis and miRNA-mediated epigenetic control of proinflammatory gene expression [181].

CONCLUSION

Interactions of cells in the innate and adaptive immune systems, and inflammatory mediators orchestrate aspects of the acute and chronic inflammation that underlie the diseases of many organs. Understanding of molecular mechanisms in those processes will not only provide important insights into the aetiology of chronic inflammatory diseases, but also provide new targets for the development of novel anti-inflammatory drugs based on triggering pathways.

Epigenetic regulation of gene expression is a novel approach to treat diseases. Epigenetic reprogramming has potential preventive and therapeutic purposes in inflammation and autoimmunity. Inhibition of histone deacetylase enzymes (HDAC) initially used in the treatment of cancer, but recent reports suggesting inhibitors of HDAC (HDACi) could be utilized in treating inflammatory diseases as well. Chromatin regulatory protein families have also provided alternative potential therapeutic targets for new anti-cancer and anti-inflammatory drugs. Many of the inhibitors that have been described to date have targeted chromatin modulators. However, their non-selectivity and consequent side effects are still limiting factors in their broader clinical use. A number of effective small molecular inhibitors of individual human methyltransferases and lysine demethylases have been developed. Inhibition of chromatin reader domains is showing great promise as a selective pharmacological strategy.

As miRNAs have been functionally connected to the development of chronic inflammation, alterations to miRNA levels could be a diagnostic way to detect the presence of chronic inflammatory states in patients. miRNAs are currently being used as diagnostics for at least some types of diseases, including some forms of chronic inflammation such as colitis and IBD. The identification of miRNAs in blood serum as well as other biological fluids, samples obtained through non-invasive methods, has opened the door for diagnosis of various diseases. Specific secreted miRNAs in the serum can be used to diagnose chronic inflammatory diseases such as IBD.

The widely use of new generation whole genome technologies and meta-analysis, lead to understand epigenetic mechanism and their roles in disease development. Enlightenment of genetic and epigenetic modifications in inflammation will guide to create new therapeutic approach in practice. However, functional studies are still emerging to validate molecular targets for smart drugs development.

Chapter 66

A NEW MOLECULAR APPROACH TO OBESITY: EPIGENETIC PERSPECTIVE

Burcu Bayoglu*, PhD and Mujgan Cengiz, PhD

Istanbul University Cerrahpasa Medical Faculty,
Department of Medical Biology, Istanbul, Turkey

ABSTRACT

Obesity is a public health problem leading to morbidity and mortality throughout the world. It arises from the interactions between genetics and environmental factors. In recent years, susceptibility to obesity has been also linked to epigenetic factors. Epigenetics, is the study of heritable changes in gene expression which do not involve in the underlying DNA sequence. The epigenetic mechanisms include DNA methylation, covalent histone modifications, chromatin folding, miRNAs, and polycomb group repressive complexes. Both dietary factors and individual behaviors affect obesity development via epigenetic mechanisms. Epigenetic mechanisms are also linked to programmed changes in gene expression as a result of early environmental exposures during pregnancy which alter offspring growth and development. There is evidence that nutrient and environmental exposures during pregnancy may affect fetal/newborn development and result in offspring obesity or metabolic syndrome which is a cluster of metabolic abnormalities. Obesity related genes, epiobesigenes, display methylation patterns playing important roles in the development of obesity which are potential future epigenetic biomarkers of obesity. The susceptibility genes have been reported as FGF2, PTEN, CDKN1A, and ESR1, functional in adipogenesis; SOCS1 and SOCS3, functional in inflammation, and COX7A1, LPL, CAV1, and IGFBP3 which are functional in fat metabolism and insulin signaling. It is important to prevent this era's epidemic, obesity, since it leads to chronic diseases including hypertension, atherosclerosis, insulin resistance, and moreover metabolic syndrome. It may be easier to prevent the progress of the disease by revealing the epigenetic mechanisms especially methylation profiles of the susceptibility genes.

Keywords: obesity, adipogenesis, epigenetics, epiobesigenic genes, DNA methylation, histon modifications

CEBPA	CCAAT/enhancer binding protein (C/EBP) a
CG	Cytosine-Guanine
COX7A1	cytochrome c oxidase subunit VIIa polypeptide 1
DNA	deoxyribonucleic acid
DNMTs	DNA methyltransferases
ESR1	Oestrogen receptor-alpha
FABP4	fatty acid-binding protein 4, adipocyte
FASN	fatty acid synthase
FGF2	fibroblast growth factor-2
FTO	fat mass and obesity associated
GLUT4	insulin-responsive glucose transporter 4
H2K4me3	trimethylation of histone H3 at lysine 4
H3K4	histone lysine methylation
H3K9	histone H3 lysine 9
H3K9me2	dimethylation of histone H3 at lysine 9
HDAC	histone deacetylase
HIF1A	hypoxia inducible factor 1
HMT	histone methylase
IFNG	Interferon γ
IGF2	insulin-like growth factor 2
IGFBP3	insulin-like growth factor-binding protein 3
INS	insulin
INSR	insulin receptor
H3-K27	lysine 27 of histone
H3	LEP, leptin
LPL	lipoprotein lipase
MC4R	melanocortin 4 receptor
miRNA	microRNA
ncRNAs	non-coding RNAs
NR0B2	nuclear receptor small heterodimer partner fibroblast growth factor-2
NPY	neuropeptide Y
NR3C1	glucocorticoid receptor; nts, nucleotides
PBMC	peripheral blood mononuclear cell
PcG	polycomb group
PcG	polycomb group proteins
PEPCK	phosphoenolpyruvate carboxykinase

PIK3CG	phosphoinositide-3-kinase, catalytic, gamma pp
PLA2G4A	plasma secretory phospholipase A(2) type IIA
POMC	proopiomelanocortin
PPARA	peroxisome proliferator-activated receptor α
PPAR γ	peroxisome proliferator-activated receptor gamma
PPARGC1A	peroxisome proliferator-activated receptor gamma-coactivator-1 α PTEN phosphatase and tensin homologue
PWS	Prader Willi Syndrome
PRC2	polycomb repressive complex 2
RARA	retinoic acid receptor- α
SOCS1	suppressor of cytokine signalling 1
SOCS3	suppressor of cytokine signalling 3
SOD3	extracellular superoxide dismutase
SSTR2	somatostatin receptor 2
HSD11B2	11 beta-hydroxysteroid dehydrogenase 2
T2D	type 2 diabetes
TNF	tumor necrosis factor
UCP1	uncoupling protein 1

1. OBESITY AND ITS MOLECULAR PATHOGENESIS

Obesity is a major health problem leading to morbidity and mortality throughout the world [1]. Obesity has a multifactorial etiology which involves interactions between genetic background, hormones and environmental factors [2]. However, the etiology of obesity is not well understood. Obesity also plays a crucial role for developing metabolic syndrome which includes insulin resistance, hypertension, elevated triglycerides and atherosclerosis [3]. Metabolic syndrome is a growing cause of morbidity and mortality worldwide. It is characterized by the cluster of metabolic disturbances including obesity, hyperlipidemia, hypertension, and elevated fasting blood sugar. The risk for metabolic syndrome has largely been attributed to adult lifestyle factors such as poor nutrition, lack of exercise, and smoking, however; there is now strong evidence suggesting that predisposition to metabolic syndrome development begins in *utero* [4]. Obesity is related with both type 2 diabetes (T2D) and metabolic syndrome development. Other than individual life style choices, there is evidence that developing obesity is in part due to genetic disposition and epigenetic alterations [5].

Body mass index (BMI) is the commonly used measure of weight status. BMI is a calculation of the ratio of someone's height and weight ($BMI = \text{kg/m}^2$).

Research have shown that, BMI is a good estimate of fatness and correlates with chronic diseases including heart disease, diabetes, cancer and overall mortality. For adult men and women, a BMI between 18.5 and 24.9 is considered healthy. BMI between 25.0 and 29.9 is defined as overweight and a BMI of 30 or higher is considered obese [6].

When energy intake exceeds energy expenditure, the excess energy is often stored as body fat and cause obesity. In recent years, it is suggested that the availability of energy-dense food, environmental changes create an obesogenic environment. Since obesity is multifactorial, an individual can become obese in the absence of an obesogenic environment or on the contrary,

an individual does not become obese in an obesogenic environment. Various factors causing obesity can be endocrine disrupters, which are the chemicals that mimic the effect of hormones in the body, and also reproductive factors including intrauterine effects, epigenetics and maternal age [7]. An obese phenotype has occurred among people in a short period of time, just one or two generations.

This shows that environmental or epigenetic factors play a major role rather than genetic mechanisms in the etiology of obesity. Although, high fat diet with decreased physical activity seems to be the strong contributor of the prevalence of obesity, some studies support that obesity may have its origin in *utero* [8-12]. Obesity and the metabolic abnormalities related with it, are developmentally programmed since, although normal postnatal nutrition is carried out, obesity exist in offspring because of the suboptimal nutrition in *utero* [13]. Similarly to type 2 diabetes, hypertension, atherosclerosis and other metabolic disorders, predisposition to obesity, and weight loss have been associated with epigenetic pattern alterations. Nutritional factors and also different non-nutritional risk factors accompanying obesity are involved in the epigenetic modifications, and they affect adipogenesis, insulin sensitivity, especially hyperglycemia, inflammation, endocrine disruptors, hypoxia, and oxidative stress [14], (Figure 1).

In recent years, the epigenetic regulation of the gene expression in obesity seems to be a potential considerable contributor. Epigenetics is defined as the study of heritable gene expression changes that occur in the absence of a change in the DNA sequence itself [15]. In other words, epigenetics is the study of gene expression's molecular control that is not caused by DNA sequence.

Modified from 14.

Figure 1. Metabolic and perinatal factors related to adipogenesis, insulin resistance.

Epigenetic modifications include methylation, covalent modifications of histones, DNA packaging around nucleosomes, chromatin folding and chromatin attachment to the nuclear matrix [16].

Epigenetics may help to understand genetic fetal programming, monozygotic twin differences, and chronic disease onset in adults, which interact with dietary intake and nutritional processes [14]. For instance, DNA sequence methylation usually reduces gene expression. Epigenetic factors may be passed on mitotically, through cell division, or meiotically, which is called transgenerational inheritance.

Thus, epigenetic programming of parental or maternal gametes, the fetus, or early postnatal development may be influenced by environmental factors [7] (Figure 2).

2. EPIGENETICS: BASIC MECHANISMS

DNA methylation, histone-tail acetylation, poly-ADP-ribosylation and ATP-dependent chromatin-remodeling are all included in chromatin-remodeling mechanisms [16]. DNA methylation is the covalent attachment of a methyl group onto the Cytosine residues' C5 position on CpG islands. CpG islands, are the genomic regions containing high number of Cytosine-Guanine (CG) dinucleotides. In the methylation of CpG islands, cytosine is converted to 5-methylcytosine and since CpG islands are mostly located on the promoter region, methylation process is often associated with gene silencing [17] (Figure 3). DNA methyltransferases (DNMTs) catalyze the addition of the methyl group to the DNA. Three major enzymes function in maintaining DNA methylation patterns.

- 1- DNA methyltransferases 3A (DNMT3A)
- 2- DNA methyltransferases 3B (DNMT3B)
- 3- DNA methyltransferases 1 (DNMT1)

DNMT3A and 3B are *de novo* methyltransferases, DNMT1 controls the methylation patterns they are copied in each cell division [18]. DNMTs interact with histone deacetylases, histone methyltransferases and methyl-cytosine-binding proteins to establish and maintain DNA methylation patterns in a complex regulatory pathway in the cell. In histone modifications, methylation of histone H3 lysine 9 (H3K9) means condensed and inactive chromatin whereas acetylation is related with active gene expression [17]. DNA methylation typically occurs during DNA replication, so that methylation patterns maintain in cell division via hemimethylated DNA. However during replication and embryogenesis, *de novo* DNA methylation can also occur [18].

To date four current models have been discussed for how DNA methylation can mediate gene silencing [19]. In the first model, DNA methylation can prevent the binding of transcriptional activator to the target DNA sequence and this directly inhibits transactivation [20]. The second model explains that the DNMT protein may link to histone deacetylase (HDAC) and histone methylase (HMT) proteins which allows the coupling of enzymatic activities [21].

Next, DNA methylation within the gene exhibits an effect of repression on transcriptional elongation. Methylation occurs generally in the promoter region, however it can occur downstream the gene too [22]. Finally, methylated DNA can be recognized directly by methyl-CpG-binding proteins. And these proteins can recruit transcriptional repressors to silence the surrounding chromatin [23, 24].

Figure 2. The interplay between environmental, genetic and epigenetic factors in the etiology of obesity.

Figure 3. DNA methylation of CpG islands.

There are also other mechanisms related with epigenetic pathways. One of them is chromatin packaging into open and closed states. The open state of the chromatin is called the euchromatin and the closed state is called the heterochromatin. DNA is packaged around histones and forms the chromatin. Histone tails are translationally modified with methylation/demethylation and acetylation/deacetylation mechanisms by histone modifying enzymes. Histone methylation may activate or repress transcription, depending on which lysine residue is methylated. For instance, trimethylation of histone H3 at lysine 4 (H3K4me3) means gene transcription is active, however dimethylation of histone H3 at lysine 9 (H3K9me2) means transcriptional silencing. Unlike methylation, acetylation activates, deacetylation represses gene expression [13, 25, 26].

An additional mechanism for the regulation of gene expression and silencing is polycomb group (PcG) complexes. PcG complexes are associated with remodeling of chromatin; for example they get involved in histone H3K27 methylation or H2AK119 ubiquitination. In this mechanism, chromatin is epigenetically repressed by these protein complexes. They are recruited to the promoter region of gene of interest and prevent transcription factors to bind the promoter of DNA sequences [27].

In the epigenetic regulation of gene expression, non-coding RNAs (ncRNAs) also take place. ncRNAs are transcribed from DNA, but they are not translated to proteins. Their main function is regulation in gene expression at the transcriptional and post-transcriptional states. ncRNAs are classified into short ncRNAs (<30 nts) and the long ncRNAs (>200 nts). Three major short ncRNAs participate in gene silencing; microRNAs (miRNAs), short inhibitory RNAs, and piwi-interacting RNAs [28, 29]. Long ncRNAs play a regulatory role during development [30]. They are expressed cell type-specific [31, 32]. Long ncRNAs are also found to be associated with adipogenesis [33, 34]. Recently, it is suggested that ncRNAs do not just regulate gene expression in translational level but also they take part in DNA methylation and histone modifications, and thus regulating the transcription of their target genes [35, 36]. Epigenetic gene silencing is also related with the microRNAs (miRNAs). miRNAs are small ncRNA genes composed of 22-nucleotides. They are specific gene regulators and control the gene expression [37]. miRNAs are transcriptionally regulated by DNA methylation and histone modifications. And so, they have significant roles in targeting key enzymes which control chromatin structure and histone modifications [17].

Epigenome is the term covering overall epigenetic state of a cell. During gametogenesis and between fertilization and blastocyst formation, epigenome may be susceptible to dysregulate [38], however during gestation, lactation and throughout life course DNA methylation patterns are maintained [39]. DNA methylation patterns change during aging process, thus a good working epigenetic homeostatic mechanism must be activated to prevent epigenetic abnormalities [40]. Otherwise, epigenetic lesions would accumulate to develop nutrition-related disorders like obesity [39]. Epigenomics is the study of genome-wide epigenetic modifications. Epigenetics is the study trying to understand relations between genes and environmental factors such as diet, inactivity, smoking, and etc. to generate a phenotype [41]. Epigenome is dynamic, since it is changed in response to nutrition, physical exercise, weight loss and aging [42-45]. In *utero* nutrition, environmental exposures, maternal or fetal stress may change the fetus's gene expression via epigenetic mechanisms, thus change the cells' and organs' structure and function leading to metabolic anomalies [13].

3. OBESITY: FROM AN EPIGENETIC PERSPECTIVE

Obesity is a multifactorial disorder involving complex interactions among genetic factors, hormones, and some environmental factors including sedentary life style and inadequate dietary habits [2]. Obesity has been associated with lifestyle and accordingly, studies have investigated thermoenergetic, life style and balance between energy intake and expenditure. Nowadays, genetic studies and molecular pathways are being investigated in obesity pathogenesis. These studies include gene mutations and polymorphisms, candidate gene approach etc [46]. Also, in recent years epigenetic regulation of gene expression has been related with obesity pathogenesis as a potential significant contributor.

There are largely animal and limited human studies reporting the association between epigenetic mechanisms and obesity. Tissue gene expression can be changed via epigenetic regulation in accordance with environmental conditions throughout life. Nutritional and environmental factors may interact with the genotype and modulate epigenetic marks in somatic cells and affect the phenotype. This is shown in monozygous twins and in *agouti* mouse.

In monozygous twins, the offspring have divergent DNA methylation and histone acetylation patterns. Lymphocyte and muscle biopsy samples were taken from 3-74 years old Spanish monozygotic twins. They are analyzed for large-scaled and locus-specific DNA methylation and histone acetylation. Older twins showed differences in their epigenetic marks and gene expression profiles; however younger twins showed no differences, suggesting that there is environmental effect on gene expression regulation, despite a similar genotype [44].

Animal obesity model of *agouti* mouse with the *agouti* viable yellow (*Avy*) mutation is used for obesity studies and this model can be modulated through an epigenetic mechanism [47]. In *agouti* mouse, the diet affects methylation status and the animal's coat color [48, 49]. In *agouti* mice, when the *agouti* gene is normally methylated, the mice are thin and have brown color. However, when the *agouti* gene completely unmethylated, the mice are obese and diabetic and also they have yellow coat color. This mutation causes the ectopic expression of the *agouti* protein. As a result of this mutation, the *agouti* protein binds to the melanocortin 4 receptor in the hypothalamus antagonistically and leads to hypothalamic dysfunction and induces hyperphagic obesity. It is known that, methylation controls gene expression, therefore, obesity phenotype depends on methylation [47]. Body weight can be affected by epigenetic regulation with dietary factors. In *agouti* mice, maternal diet with methyl supplementation affects the methylation of the *Avy* allele and offspring obesity [49]. The epigenetic regulation of hedonic reward pathways and metabolic regulation of energy balance may be changed with maternal and post-weaning high fat diet in mice and results in altering methylation of the leptin promoter in rats [50-53]. Yellow fat mice and brown thin mice have the same genotype but they have different phenotypes as a result of epigenetic alterations. These methylation patterns can also be transmitted across generations [48, 49]. Interestingly, when yellow fat mice were fed with methyl-rich diet during pregnancy, they produced offspring with brown coat without obesity. This result showed the interaction between nutrition and epigenetic modifications influencing the phenotype [54].

Epigenetic modulation of imprinted genes is also well known, for example the impact of insulin-like growth factor 2 (*IGF2*) on body weight and obesity is well studied [55]. By several autocrine, paracrine and endocrine hormonal factors, adipose tissue growth can be induced. For

the increase in adipose tissue, IGF2 expression is increased methylation of differentially methylated regions in the H19 imprinting control region. Therefore, studies on the IGF2/H19 locus showed that hypomethylated CpG islands in the 5' region of the H19 gene are critical binding sites for the 11-zinc finger protein CTCF [56]. Activation of IGF2 gene transcription is regulated via maternal diets such as low dietary protein and folate through increased methylation of ICR/H19 DMR [57]. Also, another mechanism for elevated IGF2 expression is acetylation of histone 4 (H4) at lysines 16 and 8 [58]. In this mechanism, from polycomb group proteins (PcG), polycomb repressive complex 2 (PRC2) is recruited through the interaction of CTCF with Suz12 PRC2 subunit and leads to allele-specific methylation at lysine 27 of histone H3 (H3-K27) and represses the maternal IGF2 promoters [59].

Epigenetic alterations may also occur in nonimprinted genes involved in energy metabolism. Genes functioning in adipogenesis, glucose homeostasis, inflammation and/or insulin signaling are regulated by epigenetic mechanisms, for example hormone encoding genes like, leptin; nuclear receptors like adipogenic and lipogenic transcription factors, PPAR γ and PPAR α , respectively; gluconeogenic enzymes, phosphoenolpyruvate carboxykinase (PEPCK); and transmembrane proteins, uncoupling protein 1 [53, 60-67]. For example, leptin plasma levels can be modulated by diet with epigenetic mechanisms. It is also suggested that leptin methylation affects leptin gene expression in rats since high-fat diet in rats increased the leptin gene promoter methylation in retroperitoneal adipocytes and this was related with lower circulating leptin levels [53]. Also, adipocyte differentiation and the induction of adipogenic transcription factors via epigenetic mechanisms, such as methylation of PPAR γ and C/EBP α , may drive adipogenesis. Adipocyte differentiation is also regulated by both histone lysine methylation (H3K4) and acetylation (AcH3). Increased histone trimethylation (H3K4me3) and acetylation (AcH3K9/K14) are also consistent with the PPAR γ and C/EBP α upregulation during terminal adipocyte differentiation. When H3K4me3 and AcH3K9/K14 increases, adipogenic genes may be induced contributing to early adipocyte differentiation and obesity [68-70].

Hepatic PEPCK is the rate-limiting enzyme in the metabolic pathway of gluconeogenesis. High-calorie diet causes hypomethylation of the *PEPCK* gene in rats. And this was reported to be associated with the increased *PEPCK* mRNA levels, which shows increased liver gluconeogenesis [71]. Methylation alterations were found to be associated with changes in target gene expression and glucose and lipid metabolism [13].

Recently, DNA methylation and specific histone methylation (H3K4 and H3K9) and some miRNAs were found to be related with BMI [72-74]. In a study performed with genome wide methylation analysis, human obesity was reported to be associated with methylation changes in blood leukocyte DNA [72]. Another study related with epigenetic modifications was performed in overweight individuals with and without type 2 diabetes. Histone methylation of K4 and K9 in primary human adipocytes of overweight individuals emerged 40% lower levels of K4 dimethylation in overweight nondiabetic individuals. Also, K4 trimethylation was reported 40% higher in adipocytes of overweight diabetic subjects when compared with normal-weight and overweight non-diabetic subjects. In the same study, obese and lean individuals showed varying DNA methylation levels in specific genes. Also, in cultured preadipocytes and mature adipocytes miRNA expression profiles showed different expressions [73]. Similarly, in human subcutaneous adipose tissue biopsies, differential and dysregulated miRNA expression was observed in obese and lean individuals of genome wide miRNA

profiling. In human adipose tissue, miRNA expression pattern was associated with obesity and glucose metabolism parameters [74].

In the development of obesity, animal studies were also performed to reveal the role of the epigenome. But this relation was more specific to histone modifications and miRNAs rather than DNA methylation [65, 75-78]. For example, the main adipogenic transcription factor PPAR and its target genes regulation have been associated with histone modifications (methylation and acetylation) and miRNAs, and leads to obesity, hyperphagia, and hyperlipidemia [75, 79-81]. In another animal study, maternal obesity, high-fat diet in mice were shown to increase the key transcription factor, Zfp423, which is responsible for adipogenic lineage commitment during fetal development. The repressive histone methylation, H3K27me3, was observed lower in Zfp423 promoter of fetal tissues from maternal obese mice [82].

Increased mRNA expression and CpG site/ island DNA methylation changes of pro-adipogenic factors (Zfp423 and C/EBP- β) have been shown in 3 week old rat offspring from obese pregnancies [83]. On the other hand, mice with genetically increased or decreased levels of DNA methyltransferases, DNMT1 and DNMT3b, do not gain weight or have increased adiposity. In the same study, *de novo* DNMT3a was more than doubled in white adipose tissue of obese mice, and a transgenic mouse having threefold increased *DNMT3a* mRNA levels in adipose tissue, did not show increased body weight or adiposity [84]. In that study, it was argued that, perhaps it is histone deacetylases which was functional in tissue specific expression rather than DNA methyltransferases. However, specific histone methyltransferases play a significant role in adipogenesis; mice with mutations in the histone H3, lysine 4 methyltransferase *MLL3* show decreased adipogenesis and they are protected from high-fat diet induced obesity [85]. In contrast, mice with loss of function of the H3K9-specific demethylase JmjC domain with histone demethylase 2A are obese and hyperlipidemic [75, 76]. Thus, it has been shown that mutations in epigenetic-modifiers may lead to obesity [13].

3.1. Programmed Obesity and the Epigenome

During, gametogenesis and early embryogenesis, epigenetic modifications are not completely erased. And some memory of the epigenetic state transfers to the offspring [86, 87]. This is called the transgenerational epigenetic inheritance [48]. Also, mother's nutrition or perinatal lifestyle choices in *utero* or lactation periods, may change the fetus's developmental program and may lead to obesity development in the future [88]. However the role of the nutrition on epigenetic pattern modifications during adulthood and its transfer to the gametes is still unknown [89]. So the effects of the dietary and environmental factors on DNA methylation patterns can lead to the susceptibility to develop obesity and related metabolic diseases [39].

Environmental exposures during early life may induce offspring's epigenome changes. This may lead to increased risk of obesity and metabolic syndrome in later life. Studies showed that programmed obesity in humans occurs via DNA methylation changes. Histone modifications and chromatin structure changes has not been shown yet in programmed obesity. Exposure to maternal famine or obesity decreases the DNA methylation of the imprinted *IGF2* gene in the offspring. 60-year-old adults, prenatally exposed to famine, in the Dutch Famine (1944–1945) cohort, exhibit hypomethylation of whole blood *IGF2* gene, and

hypermethylation of two obesity-related non-imprinted genes, *TNF* and leptin, compared to their unexposed, same-sex siblings. This association showed early developmental period is crucial for establishing and maintaining epigenetic marks [90, 91]. Recently, paternal obesity was found to be associated with *IGF2* hypomethylation in umbilical cord blood leukocytes of newborns [92, 93]. Also, specific maternal features like gestational weight gain and gestational diabetes have been related with signature DNA methylation in cord blood and elevated placental leptin gene methylation, respectively [42, 94]. Also, in early pregnancy maternal carbohydrate intake was related with the umbilical cord methylation levels of retinoid X receptor- α which is a nuclear receptor gene and make heterodimers with adipogenic transcription factor PPAR γ , and also related with adiposity in later childhood [95]. Animal studies show that both DNA methylation and histone modification changes are related with developmental programming of obesity in rodent models of maternal under or overnutrition; for example, high-fat diet, maternal obesity [41, 96-99]. Genes that regulate growth factors [100], adipogenesis [101], brain appetite and satiety/reward pathways [51, 102-104] and glucose homeostasis [105] have been detected to be regulated by epigenetic changes. Human and animal studies provide evidence of programmed obesity and metabolic syndrome resulting from early nutritional exposures and suggesting epigenetic modification of nonimprinted genes may be a major contributing factor [13].

3.2. Epiobesigenic Genes

In the onset, development and therapy of type 2 diabetes and obesity, epigenetic research became to have advances [16]. Some gene promoters are susceptible to epigenetic regulation and may have potential role in the development of obesity. These genes are called epiobesigenic genes [39]. Some human genes regulated by epigenetic mechanisms related with obesity are shown in Table 1.

In human obesity, many genes have been identified. These gene effects' may be modified by epigenetic mechanisms [144]. The most known example of obesity is the Prader Willi Syndrome (PWS) caused by an epigenetic mechanism in human. PWS occurs due to a lack of expression from parental chromosome 15q11-q13. This lack of expression arise from the epigenetic silencing on the maternal and paternal copy of the genes, instead of just the maternal copy, in 25% of cases. PWS is characterized with hyperphagia, infertility, and obesity [145], however obese phenotype is not passed on, due to infertility [7].

Leptin and proopiomelanocortin gene mutations also cause human obesity, and these genes have both CpG islands in which their expression can be controlled through methylation [114]. Some of these susceptibility genes are associated with various metabolic diseases like hypertension (*HSD11B2*) [134], atherosclerosis (*PPARG*) [61], diabetes (*PPARGC1*) and endotoxin tolerance [66].

Also, some of these genes may play a role in obesity since they affect adipogenesis process [61, 107-116, 134], inflammation [66, 114, 123-126, 128] and insulin signaling [66, 131-135]. When unmethylated CpG islands are hypermethylated, this means that transcriptional activation is repressed. The presence of CpG islands in the promoter region of a gene shows that, the gene might be partly regulated by CpG methylation [134]. Normal and pathologic gene expressions are being studied with methylation pattern mapping of CpG islands.

Table 1. Some human genes regulated by epigenetic mechanisms (Epiobesigenes) involved in obesity pathogenesis (Modified from 14, 39, 106)

Gene symbol	Gene name	Role in obesity	Epigenetic mechanism	Ref.
<i>PPARGC1A</i>	Peroxisome proliferator-activated receptor gamma-coactivator-1 alpha	Adipogenesis	Important in human islet insulin secretion	[107]
<i>NR0B2</i>	Nuclear receptor small heterodimer partner Fibroblast growth factor-2	Adipogenesis	Tumour suppressor methylation related	[108]
<i>FGF2</i>	Fibroblast growth factor-2	Adipogenesis	Homocysteine disrupts endothelial cells through altered promoter DNA methylation	[109]
<i>PPARG</i>	Peroxisome proliferator-activated receptor gamma	Adipogenesis	Changes in DNA methylation during cellular ageing and atherosclerosis	[61]
<i>PTEN</i>	Phosphatase and tensin homologue	Adipogenesis	Epigenetic role in colorectal cancer and gliomas	[110]
<i>RARA</i>	Retinoic acid receptor-alpha	Adipogenesis	Promoter hypermethylation associated with prostate and mammary cancer	[111]
<i>CDKN1A</i>	Cyclin-dependent kinase inhibitor 1A (p21, Cip1)	Adipogenesis and cell cycle	Aberrant promoter methylations related to cancer	[112]
<i>LEP</i>	Leptin	Adipogenesis and inflammation, appetite regulation	Post-zygotic development, adipocyte maturation and cellular ageing, DNA methylation	[53, 61, 113, 114]
<i>ESR1</i>	Oestrogen receptor-alpha	Adipogenesis	Prognostic value of Oestrogen receptor hypermethylation	[115]
<i>NR3C1</i>	Glucocorticoid receptor	Adipogenesis, stress	Methylation status is sensitive to prenatal maternal mood, Histone acetylation	[116]
<i>CEBPA</i>	CCAAT/enhancer binding protein (C/EBP) a	Adipogenesis	Histone acetylation and methylation	[117]

Gene symbol	Gene name	Role in obesity	Epigenetic mechanism	Ref.
<i>PPARA</i>	Peroxisome proliferator-activated receptor α	Adipogenesis	DNA methylation	[118]
<i>Avy</i>	Agouti	Appetite control and adipogenesis	DNA methylation	[119, 120]
<i>MC4R</i>	Melanocortin 4 receptor	Appetite regulation	DNA methylation	[121]
<i>NPY</i>	Neuropeptide Y	Appetite regulation	DNA methylation	[122]
<i>POMC</i>	Proopiomelanocortin	Appetite regulation	DNA methylation and histone acetylation and methylation	[122]
<i>TNF</i>	Tumor necrosis factor	Inflammation and insulin resistance	Epigenetic silencing during endotoxin tolerance and myeloid differentiation, DNA methylation, Methylation status is sensitive to prenatal maternal mood	[66]
<i>PLA2G4A</i>	Plasma secretory phospholipase A(2) type IIA	Inflammation	Malignant prostate cells	[123]
<i>SOD3</i>	Extracellular superoxide dismutase	Inflammation	Development of foam cells	[124]
<i>SOCS1</i>	Suppressor of cytokine signalling 1	Inflammation	Severity of liver fibrosis and hepatocarcinoma	[125]
<i>SOCS3</i>	Suppressor of cytokine signalling 3	Inflammation	Role in cellular growth and migration and melanomas	[126]
<i>IFNG</i>	Interferon γ	Inflammation	DNA methylation	[127]
<i>CASP8</i>	Caspase 8	Inflammation and apoptosis	Hypermethylation in neuroblastomas and medulloblastomas	[128]
<i>COX7A1</i>	Cytochrome c oxidase subunit VIIa polypeptide 1 (muscle)	Energy metabolism	Age influences DNA methylation	[129]
<i>LPL</i>	Lipoprotein lipase	Fat metabolism	Changes in DNA methylation during cellular ageing	[61]

Table 1. (Continued)

Gene symbol	Gene name	Role in obesity	Epigenetic mechanism	Ref.
<i>FABP4</i>	Fatty acid-binding protein 4, adipocyte	Fat metabolism	Changes in DNA methylation during cellular ageing	[61]
<i>FASN</i>	Fatty acid synthase	Lipid storage	DNA methylation	[130]
<i>CAV1</i>	Caveolin-1	Insulin signalling	Aberrant methylation is associated with hepatocellular carcinoma	[131]
<i>PIK3CG</i>	Phosphoinositide-3-kinase, catalytic, gamma pp	Insulin signalling	CpG hypermethylation is associated with progression of colorectal cancer	[132]
<i>SSTR2</i>	Somatostatin receptor 2	Insulin resistance	Tissue-specific related	[133]
<i>HSD11B2</i>	11 beta-hydroxysteroid dehydrogenase 2	Insulin resistance and adiposity	<i>In vivo</i> epigenetic repression and relation to hypertension	[134]
<i>IGFBP3</i>	Insulin-like growth factor-binding protein 3	Insulin resistance	Hypermethylation is associated with non-small cell lung cancer	[135]
<i>IGF2</i>	Insulin-like growth factor 2	Glucose homeostasis	DNA methylation and histone acetylation	[136]
<i>ADIPOQ</i>	Adiponectin	Glucose homeostasis	DNA methylation and histone acetylation	[137]
<i>GLUT4</i>	Insulin-responsive glucose transporter 4	Glucose homeostasis	DNA methylation and histone acetylation	[117]
<i>INS</i>	Insulin	Glucose homeostasis	DNA methylation and histone acetylation	[138, 139]
<i>INSR</i>	Insulin receptor	Adipogenesis, Insulin sensitivity disruption	DNA methylation	[140]
<i>FTO</i>	Fat mass and obesity associated	Body weight homeostasis	DNA methylation	[141]
<i>HIF1A</i>	Hypoxia inducible factor 1	Hypoxia	DNA methylation and histone acetylation and methylation	[142]
<i>UCP1</i>	Uncoupling protein 1	Thermogenesis	DNA methylation	[143]

Recently, primers are being designed for studying methylation patterns of genes regulated by methylation process. CpG islands of susceptible epiobesigenes are analyzed to emerge their epigenetic regulation [146]. With these analysis, it has been found that, *FGF-2*, *PTEN*, *CDKN1A*, and *ESR1* genes have enough CpG islands in their promoter region to be potential susceptibility genes for obesity and adipogenesis [147, 148-150]. In leptin regulation, *SOCS1* and *SOCS3* (suppressor of cytokine signaling 1 and 3) take place and cytokine signaling affected in obese state is attenuated [151-153]. Also, in epigenetic regulation of obesity, energy homeostasis genes, *COX7a*, *LPL*, and insulin-related genes like *CAV1* and *IGFBP3* can be potential targets [2, 154-156]. There are also other genes which do not have CpG risk sequences and have roles in body weight control [66].

For example, Glucocorticoid receptor and *TNF- α* genes are under epigenetic control but don't have remarkable CpG islands although they have significant roles in obesity pathogenesis [66, 157, 158].

CpG methylation in somatic cells may be changed by some environmental factors in postnatal life. These environmental factors may cause variation or reversibility in the DNA methylation patterns. One of these environmental factors is aging. Aging affects the DNA methylation patterns in tissue-specific way [159]. Methylation of such genes like hepatic glucokinase increases with age [160]. This shows that, DNA methylation can play a role in age-related susceptibility to hepatic insulin resistance and diabetes. Other factors influencing DNA methylation is inflammation [161], oxidative stress [162], and hypoxia [163]. In adipose tissue of obese subjects, these factors are all exacerbated [147].

In recent years, the relationship between obesity and epigenetic pathways are reported. Methylation of many genes is reversible since it can be altered by exercise or diet throughout life. Alternatively, methylation of several genes at birth are associated with obesity later in life since epigenetic regulation of inheritance may be more stable in human [164]. It has been shown that, hypocaloric diet may be associated with *TNF- α* promoter in PBMC cells [39]. Recently, studies have also been demonstrated the effects of different dietary compounds on epigenetic marks and, on gene expression regulation in disease states. Some of the nutritional factors influencing the epigenetic marks on some disease states are shown in Table 2 [14, 165].

Studies are going on to investigate the relationship between obesity, obesity related diseases and epigenetics. In a recent study, increased DNA methylation has been associated with T2D in a Swedish population [175]. Also, global DNA hypermethylation has been related with diabetic retinopathy in T2D [176].

In another study, *BCL11A* gene polymorphism has been established as a risk for T2D, and a recent study suggested a possible male gender-specific association between *BCL11A* gene methylation and T2D [177]. Besides, cholesterol and the different types of fatty acids in the diet have been shown to affect on genome-wide DNA methylation patterns [178]. Recently, a GWAS on 459 European origin individuals was performed to investigate the relationship between DNA methylation and BMI, and the analysis reported that increased BMI is associated with the elevation of methylation at the *HIF3A* locus in blood cells and in adipose tissue [179]. This study generated a support for the relationship between the epigenome and the development of obesity in genetically susceptible individuals.

Table 2. Some dietary factors influencing epigenetic marks and have beneficial effects on obesity (modified from 14, 165)

Dietary factor	Related Metabolic Disease	Epigenetic mechanism	Ref.
Methyl donors			
Methionine	Insulin resistance, obesity	Histone and DNA methylation	[166]
Folate	Insulin resistance, adiposity	DNA methylation	[166]
Vitamin B-12	Insulin resistance, obesity	DNA methylation	[166]
Serine, Glycine and Histidine	Amino acid metabolism	Histone and DNA methylation	[98]
Phytochemicals			
Curcumin	Inflammation, obesity	Histone acetylation, DNA methylation, and microRNA	[167]
Epigallocatechin 3-gallate	Obesity, insulin resistance	Histone acetylation and DNA methylation	[168]
Genistein	Obesity	Histone acetylation and DNA methylation	[169]
Sulforaphane	Adipocyte differentiation	Histone acetylation	[170]
Resveratrol	Obesity	Histone acetylation	[171, 172]
Fatty acids			
Eicosapentaenoic acid	n-3 Polyunsaturated fatty acid metabolism	DNA methylation	[173]
Docosahexaenoic acid	n-3 Polyunsaturated fatty acid metabolism	DNA methylation	[174]

CONCLUSION

In human obesity, many genes have been identified. The effects of these genes may be modified by epigenetic mechanisms. There is preliminary but compelling evidence from human and animal studies that changes in the epigenetic states may contribute to this era's epidemic, obesity. However, there are still questions remaining. Does the epigenetic analysis of a specific tissue mirror the epigenome of another tissue?, and are these epigenetic changes reversible? Further studies in epigenetics will enlighten the obesity etiology and related metabolic disease phenotypes and will provide therapeutic approaches to improve obesity prognoses.

ABSTRACT

Entomopathogenic fungi have been mentioned as one of the best alternatives for insect pest control. These fungi cause insects death. More than 750 fungal species have been described infecting insects, some of the most utilized for insect control are: *Beauveria bassiana* and *Metarhizium anisopliae*. This is evidence of cosmopolitan distribution of entomopathogenic fungi and its evolutionary success, this type of fungi is related to a serie of interactions among fungi, plants, and insects. In this chapter, the main objective is to review and discuss the most recent information on genetics and evolution of entomopathogenic fungi. In this chapter are covered the following themes: Entomopathogens role in nature, Entomopathogenic fungi and their interactions with the insect immune system, Isolation and identification of entomopathogenic fungi, Genetic diversity among strains of entomopathogenic fungus, Genes involved in virulence of entomopathogenic fungi, Molecular phylogeny of entomopathogenic fungi and their

* Corresponding Author's Email: raul.rodriguez@uadec.edu.mx.

biogeographic implications, Evolution of entomopathogenicity in fungi, Genetic improvement of entomopathogenic fungi for insect biocontrol, Future trends and Conclusions.

Keywords: isolation, identification, diversity, virulence, pathogenicity, breeding, evolution, phylogeny

ENTOMOPATHOGENS ROLE IN NATURE

Entomopathogenic are employed in different fields, to control various insect species. These fungi are widely distributed throughout the fungi kingdom. Some insect pathogenic fungi have restricted host range, while others have a wide host range, with individual isolates to be more specific (Barreto et al., 2004, Hesketh, et al., 2009). Entomopathogenic fungi have been isolated from almost all regions of the earth and almost all types of soil. This is evidence of cosmopolitan distribution and its evolutionary success, involving a series of interactions between fungi, plants, insects and other sources nutrients in their environments. Entomopathogenic fungi are distinguished from other fungi and they transmitted directly by contact with susceptible guests, rather than having to be ingested to initiate infection (Cory and Ericsson, 2010). Early studies with entomopathogenic fungi occurred in early 1800 and focused on developing ways of diseases management that were ravaging the silkworm industry in France (Vega et al., 2009).

Biological Control

Entomopathogenic fungi are a large group of microorganisms which provide a great variety of services to agro ecological systems (Téllez et al., 2009). Among these are: ability to regulate pests and also to keep them at adequate levels. Entomopathogenic fungi have great potential as control agents (Hesketh, et al., 2009), forming a group with more than 750 species, scattered in the environment and causing fungal infections with arthropod populations; among the most important genera of entomophthogen fungi are: *Metarhizium*, *Beauveria*, *Aschersonia*, *Entomophthora*, *Zoophthora*, *Erynia*, *Eryniopsis*, *Akanthomyces*, *Fusarium*, *Hirsutella*, *Hymenostilbe*, *Paecilomyces* and *Verticillium* (López-Llorca and Jansson, 2001), while for FAO (2003), the most important genera are *Metarhizium*, *Beauveria*, *Paecilomyces*, *Verticillium*, *Rhizopus* and *Fusarium*. However, Oliveira et al., 2013 mentioned that entomopathogenic fungi group includes natural enemies of insect pests and the most important genera are: *Beauveria bassiana* (Bals.) Vuill., *B. brongniartii* (Sacc.) Petch, *Metarhizium anisopliae* (Metsch.) Sorokin, *Isaria farinosa* Holms. and *I. fumosorosea* Wize, which have a wide range of insect hosts. These fungi are particularly common in soils, where often cause epizootic disease in their hosts.

The entomopathogenic fungus *Verticillium lecanii* naturally infects a wide range of sucking pests such as thrips, whiteflies, aphids and mites; these are economically important pests of major horticultural crops. By increasing the incidence level of this entomopathogenic fungus could improve the control of target pests (Visalakshy et al., 2005). Efforts to develop methods of biological control of insect pest have been pursued; one of the best entomopathogen fungi is

M. anisopliae which uses a combination of enzymes and mechanical force to penetrate the host cuticle and hemolymph, this fungus produces chitinases for invasion and as one of the host-killing components (Barreto et al., 2004). Production of enzymes, mechanical mechanisms of invasion, improved mycelia growth and formation of conidia increase the infectivity of entomopathogenic fungi as biopesticide (Visalakshy et al., 2005). Several unexpected roles have been reported by fungi entomopathogens, among them their presence as endophytes, plant disease antagonists, colonizers and rhizosphere plant growth promoting fungi (Vega et al., 2009). Entomopathogenic fungi are very important ecological components since they perform insect control functions, which is very important because mishandling of pesticides by humans has promoted that insects pest become uncontrollable and some have develop resistance to pesticides.

Table 1. Entomopathogenic fungi used in biological control

Genus	Species
<i>Metarhizium</i>	<i>M. anisopliae</i>
	<i>M. flavoviridae</i>
<i>Paecilomyces</i>	<i>P. fumosoroseus</i>
<i>Rhizopus</i>	<i>Rhizopus spp.</i>
<i>Cordyceps</i>	<i>Cordyceps spp.</i>
<i>Culicinomyces</i>	<i>Culicinomyces spp.</i>

Plants Manipulate Fungal Entomopathogens

There is scientific evidence that plants can influence behavior of certain groups of natural enemies, particularly parasitoids to increase herbivorous suppression and presumably increase the plant fitness. Plants can also influence entomopathogens in a similar manner. Entomopathogens fungi perhaps offer the best opportunities to become bodyguards of plant (Cory and Hoover, 2006). Any plant traits that improves entomopathogen fungal infection and shows a variation of genetic base could theoretically be selected as an adaptive response. For entomopathogenic fungi act as bodyguards' plant they must have benefits for plant processes (Cory and Ericsson, 2010).

The Ecology of Fungal Entomopathogens in the Rhizosphere

The ecology of fungal entomopathogens in the rhizosphere is an understudied area of insect pathology. Entomopathogenicity is a lifestyle that has emerged and lost several times in many lines of fungi (Bruck, 2010). The abundance of entomopathogenic fungi in the environment is correlated with the host abundance of species, and is facilitated by epizootic events (Cory and Ericsson, 2010).

ENTOMOPATHOGENIC FUNGI AND THEIR INTERACTIONS WITH THE INSECT IMMUNE SYSTEM

Entomopathogenic fungi are microscopic creatures living in the environment at expense of other organisms from where they get food; they are morphologically hyphae, which are cylindrical filiform structures 2 to 10 micrometers in diameter and several centimeters long, which together form a mycelium.

Classification

Two divisions are proposed: Myxomycota, those who are plasmodia, and Eumycota, which do not form plasmodia and have mycelia. Entomopathogenic fungi are located in the Eumycota division within five subdivisions; Mastigomycotina (form zoospores, or oospores), Zygomycotina (form zygospores), Ascomycotina (form ascospores), Basidiomycotina (form basidiospores) and Deuteromycotina (Ainsworth, 1973).

Important Species

According to Tellez et al., (1999), more than 750 species of entomopathogenic fungi in 100 genera have been described, the most important ones are *Metarhizium*, *Beauveria*, *Aschersonia*, *Entomophthora*, *Zoophtora*, *Erynia*, *Eryniopsis*, *Fusarium*, *Hirsutella*, *Hymenostilbe*, *Paecilomyces* (*Isaria*) and *Verticillium*; the more widely used species worldwide for biological control of insects are, *Metarhizium anisopliae* (33.9%), *Beauveria bassiana* (33.9%), *Isaria fumosorosea* (formerly known as *Paecilomyces fumosoroseus*) (5.8%) and *Beauveria brongniartii* (4.1%) (De Faria and Wraight, 2007).

Mode of Action

Entomopathogenic fungi act by contact through the cuticle, as they are able to enter and invade the insect completely, thus causing death by infection (Figure 1). According to different authors, the development cycle can be divided in two or three phases respectively; Parasitic and saprophytic (Elosegui, 2006) and infection, growth and reproduction (Boomsma et al., 2014);

adhesion and germination, penetration into the haemocoel and development of the fungus (Tanada and Kaya, 1993); adhesion, penetration and replication (Tellez et al., 2009).

Figure 1. Scheme of entomopathogenic fungal infection process to a susceptible insect. 1. Adhesion and germination. 2. Penetration of the cuticle and epidermis. 3. Reproduction. 4. Sporulation.

Adhesion and Germination

The adhesin is a molecule produced by the fungus with adherent property and comes into operation for spores adhesion to insect cuticle, this molecule is recognized by specific receptors of glycoprotein nature. Once bound to the epicuticle, spore germination phase starts in which the spore emits one or more germinating appresoria tubes. This phase is not determined entirely by the percentage of spore germination, but rather by the way of germination, type of spore, aggressiveness of the fungus and host susceptibility.

Penetration

This process is achieved through the penetration tube (hyphae) by enzymatic degradation of the cuticle involving enzymes such as proteases, aminopeptidases, lipases esterases, chitinases and mechanical pressure haustoria which deforms the cuticular layer and subsequently sclerotic that breaks the membrane areas of the cuticle. This phase is determined by cuticle hardness, thickness and presence of antifungal substances or nutrients. Even at this stage, the insect has a last defense against foreign body that is within the insect, physiological reactions such as phagocytosis, cell encapsulation and formation of antimicrobial compounds.

Reproduction and Replication

When the fungus enters the haemocoel, evades the insect immune defense through a transformation of mycelium cells to yeast, which are called blastospores, accelerating the process of reproduction and dispersal, resulting in septicemia (Pérez, 2004; Tellez et al., 2009).

Among the physiological symptoms produced by fungal infection in insects are seizures, lack of coordination in their movements, altered or abnormal behavior (stops feeding, reduces movement) and total paralysis. Death is the end result of infection due to fluid loss, physical injury and toxicosis (Bustillo, 2001).

With the insect death, the fungus parasitic phase ends, and the saprofit phase begins, where large amounts of mycelia masses emerge to the outside through natural openings like mouth, spiracles and anus as well as the intersegmental abdomen and thorax regions thereof; fruiting on the body and generating inoculum to infect other insects (Cañedo and Ames, 2004).

Each of the different stages is influenced by internal and external factors. Although most insects have defense mechanisms against entomopathogens, they somehow manage to evade and penetrate these barriers; insect defenses are considered physical, cellular, humoral and even social behavior (Marmaras et al., 1996). Some factors influence or determine behavior of the spores, when they achieved and adhere to the epicuticle host insect, such as water, nutrients or debris on the surface of the exoskeleton, ions, fatty acids and even the developmental stage of insect (larva, nymph, pupa or adult) (Hassan et al., 1989). In this matter, the insect epicuticle is well known for its hydrophobic feature, and sets the pattern as an excellent reservoir for adhesion and spore germination; however, a combination of external factors such as temperature, humidity, radiation and insect's habits determine the full or no adhesion of the fungal spore. The main ways of fungal transmission or infection that an insect is exposed are by direct contact on the ground, scattered spores in the air, contact with bodies of other infested insects and the infection routes are the oral cavity and spiracles; the entomopathogenic fungi liquid solutions that are used in modern agriculture for biological control of insects, naturally contributed to the regulation of a wide range of pests affecting world agriculture.

ISOLATION OF ENTOMOPATHOGENIC FUNGI

The fungi species of major interest for its potential as insect pathogens are: *Beauveria bassiana*, *Metarhizium anisopliae*, *M. flavoviride*, *Nomuraea rileyi*, *Lecanicillium lecanii*, *Hirsutella thompsonii*, *Aschersonia aleyrodis*, *Paecilomyces* spp., and the fungi belonging to the Entomophthorales order (Zoophthora, Entomophthora and Entomophaga). For isolation of entomopathogenic fungi, some artificial media are used such as: sabouraud dextrose agar, potato dextrose agar (PDA) and malt extract agar (MEA) (Elósegui et al., 2006). In addition, some specific media to isolate entomopathogenic fungi have been developed (Inglis et al., 2012). Different methodologies for entomopathogen fungi isolation have been developed.

Isolation by Serial Dilution

This method involves placing a mycosed insect in a vessel containing 10 ml of Tween 80 (0.01%) in sterile distilled water. The resulting suspension has to be stirred for 1 minute to release conidia insect body. As a result, there is obtained a concentrated suspension or stock solution of inoculums with other particles. The stock solution can be used to prepared serial dilutions. The first dilution (10^{-1}) can be obtained by mixing 1 ml of the stock solution in a tube containing 9 ml of Tween 80 (0.01%) in sterile distilled water. This operation is repeated

several times until a dilution series (10^{-1} to 10^{-6}) are obtained. For inoculating and obtaining fungus, the latest dilutions (10^{-4} , 10^{-5} , 10^{-6}) are used. Subsequently, they are inoculated in Petri dishes with 100 μ L of PDA medium and incubated at $25 \pm 1^\circ\text{C}$ for 5 to 7 days. Once the fungi are grown, the next step is to identify them, especially some of interest (primarily *Metarhizium anisopliae*, *Beauveria bassiana* and *Entomophthora* spp.). Identification can be accomplished using a compound microscope and dichotomous keys based on morphological characteristics of reproductive structures, such as conidiophores, conidia and phialides.

Direct Isolation of Entomopathogenic Fungi from Insects

For direct isolation, it is necessary to monitor the culture of interest. For this, dead insects, suspected of fungal infections with mummification symptoms, or sporulation of fungal nature in the cuticular surface have to be collected (Diaz et al., 2008). Samples are handled with soft tweezers and placed into microcentrifuge tubes (depending on the size of the insect). In aseptic conditions, insects are disinfested in a solution of 2% sodium hypochlorite for 3 minutes and rinsed three times with sterile distilled water. Such type of isolation can be done in two ways: first, by scraping with a bacteriological loop all fungal particles present in a disinfested insect, and then passing them in Petri dishes with PDA culture medium through the technique of rifling; second, with a dry, sterile forceps, take the sporulated insect previously disinfested and shake it with vertical and horizontal movements on the surface of Petri dishes with PDA medium and incubated at $25 \pm 1^\circ\text{C}$ for 5 to 7 days. Once fungal growth is observed, proceed to the characterization.

Isolation of Entomopathogenic Fungi from Soil

Insect trap technique which use in most cases *Galleria mellonella* (Lepidoptera: Pyralidae) and *Tenebrio molitor* (Coleoptera: Tenebrionidae) (Zimmermann 1986); these insects are reproduced under lab conditions besides they are susceptible to fungi. Soil samples are collected from depth of 0-20 cm and placed in properly labeled plastic bags. At each site a subsample is taken, in order to form a composite sample of 1 kg. From each sample of homogenized soil, 500 g are taken and placed in a plastic container of $14 \times 18 \times 6$ cm with seven larvae of *G. mellonella* or *T. molitor* of last stage and incubated at $25 \pm 1^\circ\text{C}$ for 7 days. Subsequently, the dead larvae with symptoms of fungal infection are placed in a moist chamber. Isolation and purification of the fungi is performed in a laminar flow chamber for direct transfer of conidia and/or mycelia in Petri dishes containing PDA medium with 100 μ g streptomycin sulfate and 10 μ g of tetracycline hydrochloride (antibiotics) (Khudhair et al., 2014). After incubation, observation of fungal growth is performed to identify them with keys based on morphological characters of reproductive structures, such as conidiophores, conidia and phialides.

MORPHOLOGICAL CHARACTERISTICS OF ENTOMOPATHOGENIC FUNGI

Beauveria bassiana

Colonies on PDA at the beginning are white and fluffy, become beige slightly and dusty and eventually sporulate. On the reverse side, they are slightly yellow. This fungus has abundant conidiophores with dense groups of phialidic cells, conidiogenous and globose cells, both bottle shaped with intermediate forms, $1.5\text{--}3.0$ ($2.7\text{ }\mu\text{m}$) $\times$ $2.0\text{--}3.0$ ($2.2\text{ }\mu\text{m}$) and hyaline conidia, sometimes with a very definite globose to ellipsoid apex $1.5\text{--}3.0$ ($2.3\text{ }\mu\text{m}$) $\times$ $1.5\text{--}3.0$ ($2.1\text{ }\mu\text{m}$).

Metarhizium anisopliae

This fungus has white and cottony colonies on PDA, in the beginning turn greenish yellow and finally dark olive green and crusted with areas with abundant white aerial mycelium. The reverse of the Petri dish is intense yellow. Also it has conidiophore typical pattern with 2-3 whorled branches each, with dark olive green tones but, clarifies the apex. Others characteristics of this fungus are conidiogenous cells $6.0\text{--}10.0$ ($8.1\text{ }\mu\text{m}$) $\times$ $2.0\text{--}2.5$ ($2.1\text{ }\mu\text{m}$), subhyaline to slightly green, and cylindrical to slightly ellipsoidal conidia, $5.0\text{--}8.5$ ($6.6\text{ }\mu\text{m}$) $\times$ $2.0\text{--}3.0$ ($2.4\text{ }\mu\text{m}$).

Paecilomyces lilacinus

Colonies of this fungus on PDA at the beginning are downy white, then they turn in gray to purple depending on age and shown an irregular aerial mycelium. On Petri dish reverse, it is observed a red color. Alone or in groups, conidiophores form synnemata with whorls of up to six phialides, which with age become wrinkled. Typical conidiogenous cells, $7.0\text{--}13.0$ ($9.5\text{ }\mu\text{m}$) $\times$ $1.5\text{--}3.0$ ($2.8\text{ }\mu\text{m}$) have catenulate conidia, light gray-violet, ellipsoidal to fusiform, some with an apex, $1.5\text{--}3.0$ ($2.2\text{ }\mu\text{m}$) $\times$ $1.5\text{--}3.0$ ($2.4\text{ }\mu\text{m}$).

***Nomurae rileyi* (*Metarhizium rileyi*)**

This fungal species grows slowly in culture medium (Sabouraud-maltose agar) showing initially a pale green colony, changing its conidia into malachite green or olive green as they mature. Vegetative hyphae are septate, smooth, hyaline or slightly pigmented wall; its reproductive structure is a septate conidiophore born from hyphae forming dense clusters with groups of 2 or 3 compacted phialides around the conidiophore, the phialides are cylindrical with occasionally flared base and very short neck or absent of $4.7\text{--}6.5 \times 2.3\text{--}3\text{ }\mu\text{m}$. Conidia in chain are ellipsoid or sometimes cylindrical of $3.5\text{--}4.5 \times 2\text{--}3.1\text{ }\mu\text{m}$ (Samson, 1974). Mainly limited to the Lepidoptera order: *Spodoptera frugiperda* and *Helicoverpa armigera* (Adsure

and Mohite, 2015), and at least two species of beetles: *Hypera punctata* (Fabricius) and *Leptinotarsa decemlineata* (Kroatz).

Lecanicillium (=Verticillium) lecanii

In potato-carrot agar, the colonies of this fungus are fluffy and white. Solitary or whorled and prostrated conidiophores, carrying a hyaline apical mass of subglobose, oval, falcate, fusiform and unicellular subcolumnar conidia, non-adhesive and do not exhibit latent structures (Zare et al., 2001). Conidia with dimensions between 6.2 to 11.3 μm diameter, and phialides from 11.2 to 30 $\times$ 1.7-2.5 μm , the conidia are 3.0 to 4.0 μm width and 5.8 to 10.5 μm length (Sugimoto et al., 2002). This fungus has a wide host range: Hemiptera insects (*Toxoptera aurantii*, *Aphis gossypii*, *Myzus persicae* and *Bemisia tabaci*), Coleoptera, Diptera and Lepidoptera orders and mites of *Tetranychidae* family.

Isaria fumosorosea

This fungal specie presents yellowish hyaline, septate hyphae with thin walls. Most *I. fumosorosea* isolates have whorled or irregularly branched, carrying in its terminal part at each branch phialides groups, which can also be lonely. Its phialides have a cylindrical or swollen basal portion, often abruptly tapering to form a very noticeable neck. Conidiophores carry conidia chains; these are hyaline, unicellular and ovoid (Bustillo, 2001). This entomopathogenic fungus is characterized by bright colors like white, yellow, pale green, pink, red or purple. It has hyaline to yellowish, septate hyphae with smooth walls. The conidiogen structure is a synnema or monosynnema consisting of compacted hyphae, irregular and whorled conidiophores with terminal branches, which clusters widened bottle-shaped with a distinct neck where the conidia are born, which grow as chain in a basipetal form by a cell, rarely two, hyaline or slightly pigmented with smooth, echinulate walls or more forms (Berlanga, 1997; Hernandez, 1997). *I. fumosorosea* is used to control mainly *Bemisia tabaci* and *Diaphorina citri* (Flores et al., 2013).

Hirsutella thompsonii

This fungal specie presents septate, fine and hyaline mycelium with a diameter from 1.7 to 3.3 μm . Hyphae usually develops in a simple form except in species producing synnema, sporulates moderately, its conidiogenous cell is a gray phialides, from 10 to 15 μm long, originating from the sides of hyphae. The conidia are spherical from 2 to 4 μm diameter with verrucose surface (McCoy, 1981). Growth in malt agar medium, has an abundant mycelial mass and subsequently acquires light gray shades between gray and bluish gray with presence of hyaline droplets of liquid and white synnemata over 10 cm in length (Cabrera and Dominguez, 1987). *H. thompsonii* is specific to mites, mainly Eriophyidae and Tetranychidae, and it has been reported on plowman of citrus *P. oleivora* in the United States, China and Cuba (Samson et al., 1980); *E. gerreronis* in coconut in Cuba and Mexico and other citrus mites and cherry,

in laboratory *Tetranychus cinnabarinus*, *Eutetranychus orientalis* and *Tetranychus turkestan* are susceptible (Gerson et al., 1979).

Aschersonia aleyrodis

Colonies of this fungal specie on PDA grow slowly reaching 35 mm in diameter in three weeks at 23°C, filamentous white to yellowish white hyphae, sometimes with a grayish-yellow color with peripheral circle. Conidia masses of variable color, light, intense or reddish orange. Most conidia measure $10\text{--}16 \times 1.0\text{--}1.5 \mu\text{m}$, thick-walled hyphae, or in a whorl of 2-6 from the end of the thick-walled hyphae; conidiophores with multiple ramifications of 35-65 μm , some elongated phialides that reach paraphyses (Liu et al., 2006). *Aschersonia* species form a simple small stroma which consists of a dense interweaving hyphal of thick wall forming a structure or a fruiting body called pycnidium, in which conidia are produced. Different species of this fungus can be distinguished by the color of the stroma and conidia, which presents a red, brown, orange or yellow tonality. The conidia have little variation in shape, being generally fusoid or oval with pointed ends (Mains, 1959). *A. aleyrodis* is reported by infect midge benches of agricultural importance highlighting *Dialeurodes citrii*, *D. citrifolii*, *Bemisia tabaci* (Genn), *Trialeurodes floridensis* (Quaintance) *T. vaporariorum* (Westw) *Aleurocanthus woglumi* (Ashby) and *Aleurothrixus floccosus* (Mask) (Hernandez et al., 2005).

Entomophthora muscae

The species are subspherical, ellipsoidal, kidney-shaped or rounded bodies hyphae measuring $24\text{--}54 \times 17\text{--}41 \mu\text{m}$ with 10 to 24 nuclei (average 15-19). Conidiophores are unbranched and contain 10 to 27 nuclei (average 15 to 20). Primary conidia average measured is $27 \text{ to } 31 \times 20 \text{ to } 24 \mu\text{m}$ with a length/diameter ratio of 1.20-1.32 and 10 to 27 nuclei (average 15-20) relationship. The secondary conidia average measured is $19\text{--}24 \times 15\text{--}19 \mu\text{m}$ with a length/diameter ratio of 1.20-1.33 (Keller et al., 1999). *Bemisia tabaci*, *Aphis fabae*, *Acyrtosiphon pisum*, *Delia radicum*, *Pollenia angustigena*, *Coenosia tigrina*, *Musca domestica*, *Scatophaga stercoraria*, Syrphidae and Anthomyiidae. (MacLeod et al., 1976; Jensen et al., 2006) are controlled by *E. muscae*.

MOLECULAR IDENTIFICATION OF ENTOMOPATHOGENIC FUNGI

There are several molecular techniques for DNA analysis and search for information to identify entomopathogenic fungi. Among the most important techniques are RAPD's (Random Amplification of Polymorphic DNA) or AFLP's (Amplification Length Polymorphism Fragments). For these techniques, combinations of primers (oligonucleotides) that produce different banding patterns can differentiate DNA from different individuals (Bulat et al., 2000). On the market are available kits with universal oligonucleotides for microorganisms and plants, which can be used for fungi. It is also possible to design PCR protocols to amplify the internal

transcribed spacer regions (ITS) which can be cut using enzymes. It is known that ITS are highly conserved in all organisms, so small changes in them can be used for classification. There are PCR-based primers used for characterization of specific entomopathogenic fungi such as *B. brongniartii* (Enkerli et al., 2001), *B. bassiana* (Rehner and Buckley, 2003), *M. anisopliae* (Enkerli et al., 2005), as well as *Isaria fumosorosea* (Gauthier et al., 2007).

Ribosomal RNA (rRNA) and its template ribosomal DNA (rDNA) sequence comparisons are useful for estimating both close and distant relationships among fungi. Small subunit rRNA gene (18S rDNA and 5.8S) sequence divergence has contributed in phylogenetic analysis among distantly relaxed taxa; however, those sequences are generally too conserved and attempts have been made to utilize the more variable domains of the large subunit (26 or 28S) for species identification and detection. Since 2012, the internal transcribed spacers of the nrDNA (ITS) are accepted as the official DNA barcode for fungi (Schoch et al., 2012). The high number of copies of the ITS per cell, in particular, makes it an attractive target for diagnostics and it can be detected with great sensitivity. Nevertheless, a secondary identification marker is sometimes needed and calmodulin (CaM), β -tubulin (benA) and the RNA polymerase II second largest subunit (rpb2) have been suggested for this purpose (Samson et al., 2014). The rpb2 gene is not easy to amplify, rendering its use as secondary identification marker frustrating. In contrast, benA is easy to amplify, but has been reported to vary in the number of introns and PCR sometimes results in the amplification of paralogous genes (Peterson, 2008; Hubka and Kolarik, 2012). In addition, the CaM sequence database is almost complete for all accepted species.

GENETIC DIVERSITY AMONG ENTOMOPATHOGENIC FUNGAL STRAINS

Diversity of entomopathogenic fungi is determined in an ecological community by ecological indices based on morphological characteristics. However these indices are not enough to determine the genetic diversity within communities (Garrido-Jurado et al., 2015). Genetic diversity and population structure are required to understand and direct the use of fungi as biological control agent. The overall genetic diversity in entomopathogenic fungi resulted from the genetic variation within geographical populations. This genetic diversity correlates with presence or absence of recombination.

Molecular tools can be used to identify the genetic differences between and among fungal species (Garrido-Jurado et al., 2015) which can allow understanding population structure and gene flow within communities. The genetic variability has been studied using several molecular markers such as RFLPs (length polymorphisms of restriction fragments), RAPD (DNA polymorphisms amplified random), minisatellites, AFLP (Amplified Fragment Length Polymorphism), SCAR (sequence-characterized amplified region), SSR (simple sequence repeats or microsatellites), ISSR (inter-simple sequence repeat), SSCP (single-strand conformation polymorphism), TGGE (temperature gradient gel electrophoresis) and DGGE (denaturing gradient gel electrophoresis) (Enkerli and Widmer, 2010; Guo, 2010). Specific DNA sequences are used as genetic markers and allow to discriminate within taxonomic groups a community structures and the phylogenetic relationship, or characterization and monitoring of strains in different environments can be studied (Enkerli and Widmer, 2010). Genetic

variability in several species of *Beauveria* sp, *Metarhizium* sp, *Paecilomyces* sp. and other entomopathogenic fungi has been evaluated by several molecular techniques.

Garrido-Jurado et al., (2015) analyzed the diversity of entomopathogenic fungi during four seasons in olive orchards, holm oak reforestation, holm oak dehesa and sunflower plantation. In this study were identified entomopathogenic fungi species such as: *Beauveria amorpha*, *B. bassiana*, *B. pseudobassiana*, *B. varroae*, *Metarhizium brunneum*, *M. guizhoense*, *M. robertsii*, *Paecilomyces marquandii* and *lilacinum* using gene EF-1 α sequences and ISSR. The Shannon–Wiener index was used to measure diversity and abundance in the eco-system. The ISSR and ITS analysis revealed a high degree of polymorphism among the different isolates with 80% of polymorphic bands particularly in all species of *B. bassiana*; which was dominant in all cropping system and all seasons. In some studies, it has been found differences among communities of entomopathogenic fungi in different types of soils such as *Beauveria bassiana* in forest soil and *Metarhizium anisopliae* in cultivated soil; these differences reflected a high level of DNA polymorphism (Garrido-Jurado et al., 2015).

***Beauveria* spp**

In this fungal specie were used molecular markers such as RAPD to determine the genetic diversity among isolates from different geographical regions of Chile. The RAPD analysis indicated high genetic diversity with 43% similarity between isolates, indicating that genetic diversity was not associated with the geographical origin of the isolates (Becerra et al., 2007). Fernandes et al., (2009) evaluated the genetic diversity among 49 species of *Beauveria bassiana* from Brazil and 4 species of *Beauveria* spp. from USA. The isolates were analyzed by ITS (including the 5.8S gene) and AFLP and revealed considerable genetic variability among *B. bassiana* isolated from different geographical regions of Brazil, and differences between Brazilian and USA *B. bassiana* isolates. Other study reported the genetic diversity in *Beauveria*, where were used 82 polymorphic AFLP loci; several alleles were found in the *Beauveria* strains as alleles 2 and 5 in the locus MDH in all strain, allele 3 in the loci PGM and 6PGD in 96% of *B. bassiana*, allele 2 in the locus G2D in 90%, allele 2 and 3 in the loci FUM and PK in the 88% and allele 1 in IDH to 86%. The geographical distance between entomopathogenic fungi demonstrated notable genotypic variation but no correlation was observed according to the host (Fernandes et al., 2009).

SSR markers are often highly polymorphic and can be used for genotyping of different fungal strain and monitor entomopathogenic fungus in different environments. Reineke et al., (2014) monitored *Beauveria bassiana* in different environments using SSR markers and found that SSR were important tools to monitor fungal strain. The microsatellite primers used were Ba01, Ba02, Ba08, Ba12 and Ba13. *B. bassiana* strains from different origin shared the same alleles at 5 SSR loci, among them 18 isolated strains, 3 strain from India and 2 from the USDA culture collection.

Meyling et al., (2009) identified *B. bassiana*, *B. brongniartii* and a monophyletic group nearby from *B. bassiana*. The entomopathogenic fungi were collected from insects sampled in cultivated field and soils in Denmark; for the phylogenetic analysis were used some markers identified from *B. bassiana* such as Ba06, Ba08, Ba12, Ba13, Ba15, Ba18, Ba21, Ba26, Ba27 and markers isolated from *B. brongniartii* such as Bb1F4, Bb2A3, Bb2F8, Bb4H9, Bb5F4 and Bb8D6. The same authors determined multilocus microsatellites for five phylogenetic

species of *B. bassiana*; these species co-exist on the sites of collect. The five population showed multiple allelic differences of microsatellite loci by EF-1 α phylogenetic analysis; the Eu_3, Eu_4, Eu_5 and Eu_6 populations had low allelic variation, only show 1, 2, 5 and 2 polymorphic loci respectively, while the population Eu_1 had the greatest genotypic variability with 12 polymorphic loci. This variability could be attributed to recombination; also they found that *Beauveria* diversity was highest in the semi natural habitat because of great abundance and diversity of insect hosts. The semi-natural habit had increased humidity and environmental stability compared with the agricultural field.

The virulence of 21 isolates of *B. brongniartii* and 2 isolates of *B. bassiana* was evaluated against adults and larvae of *Schizonycha affinis* and *Hypopholis sommeri*, respectively. The isolates of *B. brongniartii* showed low level of genetic diversity using microsatellite markers. In this study, it was found that 21 isolates of *B. brongniartii* represent 17 haplotypes and that were genetically close. The isolates of *B. brongniartii* may vary in their virulence with a mortality of 50.1–95% to *S. affinis* and 39–74% of mortality to *Tenebrio molitor* (Goble et al., 2015).

***Metarhizium* spp**

The fungus is usually isolated from soil, but the distribution of species in soil is unknown. The phylogenetic relationship and genetic diversity of *Metarhizium* spp. isolated from *Schiodtella formosana* were analyzed by ISSR. The 86% of the generated bands were polymorphic and the polymorphic loci P was from 70 to 100%. The *Metarhizium* populations were differentiated into 2 clades, reflecting a proportion of 79.2% of gene differentiation within the populations. The isolates of *Metarhizium* spp. were identified based on ITS sequences in *M. anisopliae* var. *anisopliae* and *M. robertsii* (Luan et al., 2012).

In diverse Asia and European countries was determined the genetic diversity of *Metarhizium anisopliae* by microsatellite markers (SSR) and ITS rDNA regions (ITS-1, ITS-2 and 5.8S gene regions). Using SSR was found that existed a low level of polymorphism in *M. anisopliae*, gene diversity was 0.37 and the result of ITS-rDNA sequence confirmed that SSR had minimal genetic variation in all isolates with a genetic distance of 0.34%, the closely related genotypes of *M. anisopliae* were dominant in different ecosystems in regions of China (Freed et al., 2011).

Metarhizium spp. were obtained from bulked soil samples of agricultural field and surrounding hedgerow in single agro ecosystem in Denmark. The genotypic diversity of *Metarhizium* isolates was analyzed by SSR and it was found co-occurrence of four species in the soil of the smaem agro ecosystem. To determine the different genotypes were used 18 SSR markers: Ma145, Ma325, Ma307, Ma2049, Ma2054, Ma2055, Ma2056, Ma2057, Ma2060, Ma2063, Ma2069, Ma2070, Ma2077, Ma2089, Ma2283, Ma2287, Ma2292, and Ma2296. *Metarhizium brunneum* was most frequent (78.8%) followed by *M. robertsii* (14.6%), while *M. majus* and *M. flavoviride* were infrequent (3.3% each). Based on SSR analysis were identified 5 genotype of *M. brunneum* and 6 genotypes of *M. robertsii* indicating particular adaptations to these soil environments (Steinwender et al., 2104).

SSR markers were used to characterize polymorphisms in one collection of 65 strain of *Metarhizium*. These strain included *M. anisopliae*, *M. brunneum*, *M. guizhouense*, *M. lepidiotae*, *M. majus*, *M. pingshaense* and *M. robertsii*, represent more of 75% of the strain

isolated and were amplified using 21 markers (15 polymorphic) based on EF1 α sequence (Mayerhofer et al., 2015). Bischoff et al., (2009) evaluated phylogenetic relationships within *M. anisopliae*, *M. taii*, *M. pingshaense* and *M. guizhouense* by EF-1 α , RPB1, RPB2, IGS and β -tubulin gene regions.

***Paecilomyces* spp**

Genetic relationship of several isolates of *Paecilomyces fumosoroseus* from various host species and geographical locations was investigated; the isolates of *P. fumosoroseus* from *Bremisi tabaci* indicated the association of genotypes with this insect. The analysis of allelic variability by microsatellite loci allowed group in two lineages, one lineage included genotypes related to *B. tabaci* in America and other lineage distributed in Asia (Gauthier et al., 2007). Other specie of *Paecilomyces* in which genetic diversity was evaluated by SSR markers was *Paecilomyces variotii*. The isolates were obtained from pistachio gardens and were identified 22 alleles; this allowed grouped all the isolates into 8 groups with high genetic variability but not demonstrated the relationship between isolates and the geographical regions of collect; the SSR primers PfrBtB04 and PfrBtD05 amplified alleles at numerous loci (Ebrahimi et al., 2015). In addition, genetic diversity of *P. variotii* was examined by SSR analysis using the primers PfrBtD11a, PfrBtD11b, and PfrBtB04 and RFLP analysis. The polymorphism information content and marker index were calculated; in this study was evaluated the amount of detectable polymorphism in the isolates, RFLP produced 20 loci con 90% of polymorphism and SSR produced 32 loci with 37.5% of polymorphism (Rostami et al., 2015).

Paecilomyces liliacinus is other specie in which was analyzed the degree of polymorphisms and haplotype diversity. Li et al., (2013) analyzed 80 specimens of *P. liliacinus* and observed diversity among six gene fragments and the haplotype h18 which was the most common in 20 isolates. Besides, it was found an extensive gene flow among strains. The phylogenetic trees based on the six gene fragments allowed grouping the strains in four clades. Evaluation of composition and dynamic of entomopathogenic fungi populations may improve the effects of entomopathogenic fungi for biocontrol. In addition, resolution of genetic markers allows description of population structures and help to understand local migration and dissemination patterns.

GENES INVOLVED IN VIRULENCE OF ENTOMOPATHOGENIC FUNGI

Entomopathogenic fungi comprising a group of approximately 100 genera, however, a low percentage is used for pest control. It is important to know that genes involved in the virulence of entomopathogenic fungi, with the objective of genetic manipulation and decrease of agricultural losses (Sansores-Lara et al., 2014). Most fungal species used for biological control are *Beauveria bassiana*, *Metarhizium brunneum*, and *M. anisopliae*.

The virulence of entomopathogen fungi involves adhesion, germination, differentiation and penetration steps. Particularly, genes involved in virulence from *Beauveria bassiana* are distributed in the seven step of infection, as follow: host adhesion, germination, cuticle

degradation, growth as blastospores, host colonization and killing, immune response interactions and hyphal extrusion and conidiation. During this procedure, 53 genes are expressed and correspond to hydrophobin, mitogen-activated protein kinase (MAPK), protein kinase, subtilisin-like protease, chitinase mannitol-1-phosphate dehydrogenase, regulates calcium sensor (acidification regulator), beauvericin toxin, bassianolide toxin, bassiacridin, among others (Valero-Jiménez et al., 2016).

In cuticle degradation and hyphal extrusion and conidiation, a chitinase gene (Bbchit1) is related. (Fang et al., 2005). The Bbchit1 from *B. bassiana* has a length of 1047 bp and encode for a protein of 348 amino acids, where the 28 amino acid residues corresponding to signal peptide. Later, a hybrid protease was development by fusion of a chitin binding domain BmChBD from *Bombyx mori* chitinase to the C-terminal of CDEP-1, a subtilisin-like protease from *B. bassiana*. The hybrid was able to increased fungal virulence compared with the wild-type native protease (Fan et al., 2010). Since glycosidase hydrolase family 18 of the *M. anisopliae* has been studied for importance in virulence. Family 18 and 19 are responsible of hydrolysis of chitin present in the insects, and have been identified 24 genes belonging to family 18, including chit1, chi2 and chi3 (Junges et al., 2014).

Other gene that regulates fungal conidiation, virulence and stress control in *B. bassiana* is Ras homologs (Ras1, Ras2 and Ras3). Ras1 and Ras2 genes have length of 648 and 708 bp, which encodes for 216 and 236 amino acid, with molecular mass of 24.3 and 26.2 kDa, respectively (Xie et al., 2013). The Ras3 GTPase gene is localized in plasma membrane and is involved in the HOG1 pathway necessary for osmoregulation. By the way, the Ras3 can be regulating conidiation, germination, multi-stress tolerance and virulence (Guan et al., 2015).

Two hydrophobins encoded by hyd1 and hyd2 genes, which have been detected in *B. bassiana*, can be involved in cell surface hydrophobicity, adhesion, virulence and constitute the spore coatrodlet layer in fungi (Zhang et al., 2011). The hydrophobin gene (*hyd1*) promoter (GenBank ID:GU936631) has a size of 1798 bp, however a truncated 1290 bp fragment (*Phyd1-t1*) was used for eGFP expression (enhanced green fluorescence protein) which was decreased. In addition, an insect midgut-specific toxin gene (*vip3Aa1*) was expressed in transgenic strains of *B. bassiana* (BbHV8, BbV28 and Bb2860), where BbHV8 strain produced nearly 10-fold more toxin molecules in conidia and thus killed *Spodoptera litura* larvae more rapidly and effectively irrespective of normal or heat-killed conidia ingested (Wang et al., 2012). On the other hand, in *Metarhizium brunneum*, three genes with relationship virulence (HYD1, HYD2 and HYD3) were reported, which codified for hydrofobines class I and class II (form rodlet structures at interfaces and do not, respectively). These genes were deleted in the fungi and conidia or blastospores of each mutant were applied versus *S. exigua* larvae. Reductions in virulence and delayed mortality were presented in comparison with wild-type strain (Sevim et al., 2012).

Adhesin genes (MAD1 and MAD2, adhesion-like protein) from *M. anisopliae* are responsible for anchor to insect cuticle and facilitate the colonization. Full length genes are 2151 bp and 306 bp that encode for 717 and 306 amino acids (Wang and St-Leger, 2007). Other entomopathogenic fungus enzyme related with cell-surface localization and host adhesion is glyceraldehyde-3-phosphate dehydrogenase (GAPDH) with 338 amino acids. However the gene (*gpdh1*) is a full length of 1230 bp (GenBank id: EF050456) (Broetto et al., 2010).

A mitogen-activated protein kinase (MAPK) regulates the fungal development, growth, and pathogenicity over insects (Luo et al., 2012). According to Koduru et al., (2014), protein osmosensor (MOS1), laccase, superoxide dismutase (Bb-SOD2), mutation in β tubulin genes

and adenylate cyclase, are related in abiotic stress and virulence of insect pathogenic fungi. A MAPK gene was identified in *B. bassiana* (Bbmkp1), which is essential for spore adhesion, formation of appressoria and ability to cross the insect cuticle both during infection and exit after insect death. Other gene with same action is an HOG (high osmolarity glycerol response) kinase. Both genes affect the transcript levels of hydrophobin encoding genes (Koduru et al., 2014). Bbslt2 gene (GenBank: JF932503.1) is required for full virulence in *B. bassiana*. This gene has a length of 1257 bp, which encode for a protein of 418 amino acids that correspond to Slt2 family MAPK (Luo et al., 2012).

Recently, a correlation between Pr1 and Pr2 gene associated to virulence of *M. anisopliae* strains has been established. These genes encode for proteases such as subtilisin-like enzyme (Pr1) and trypsin-like enzymes (Pr2), these enzymes are important for insect cuticle degradation. A bioassay of mortality was performed with four strains of *M. anisopliae* (6342, 6345, 6347 and 798), which possess 11 pr1 genes, versus adults of *Prosapia* sp. and larvae of *Spodoptera exigua*. The highest mortality (73%) on this insect was generated by the 6342 strain, which showed the maximum Pr2 enzymatic activity. However, subtilin and trypsin production are not indispensable for pathogenicity (Rosas-García et al., 2014). In addition, Ifa-Pr1A gene from *Isaria farinose* (GenBank id: JN014832) was detected using the RACE technique with a length of 960 bp, which encode for a protein of 320 amino acids. The Ifa-Pr1A transcripts exhibit 58 800-fold at 12 h post-induction. Therefore, the gene is considered as major cuticle-degrading proteases in the studied fungus. Besides, the Ifa-Pr1A gene is an important virulence factor for the development of biopesticides (Wang et al., 2013). An *in vivo* infection study of insects (*Galleria mellonella*, *Eupoecilia ambiguella* and *Cactoblastis cactorum*) infected by *B. bassiana* revealed the expression of three genes: subtilin (Pr1h), exocyst component (Sec15) and EC391425 with a length of 98, 160 and 120 bp (Galidevara et al., 2016). The same gene from *M. acridum* and *M. anisopliae* has been described as heavily involved in the initial steps of fungal invasion of arthropod-host cuticle (Leão et al., 2015; Golo et al., 2015).

During immune response interactions, a superoxide dismutase is expressed in *B. bassiana* 2860. The BbSod2 gene (630 bp) from *B. bassiana* 2860 encodes a 209-aa protein with a theoretical molecular mass of 23.1 kDa and isoelectric point of 7.14. (Xie et al., 2010). Secondary metabolites tenellin (BbtenS), beauvericin (BbbeaS) and bassianolide (BbbslS) were measured by quantitative reverse transcription real-time PCR (qRT-PCR) during infection of *Triatoma infestans* (Chagas disease) by the entomopathogenic fungus *B. bassiana*. BbtenS and BbbeaS were highly expressed at days 3 and 12 post-treatment. In blastospore-injected insects, BbtenS and BbbeaS expression peaked at 24h post-injection and were also highly expressed in insect cadavers (Lobo et al., 2015).

The methyltransferase (mtrA) have a role in fungal physiological process. The mtrA gene (921 bp) encoding a protein of 307 amino acids (molecular mass 36 kDa, GenBank accession number EJP69472) in *B. bassiana*. Insect bioassay using wild-type *B. bassiana*, Δ BbmtrA, Δ BbmtrA : : mtrA strains on larvae of the greater wax moth, *G. mellonella*, revealed that median lethal time (LT₅₀) for wild-type strain is the 7.2 days and 80% of mortality, these values is decreased in Δ BbmtrA : : mtrA strains with values of 10 days and 60% for LT₅₀ and mortality, respectively (Qin et al., 2014). Actually, an insect-toxic protein (Bb70p) from *B. bassiana* was assayed versus *G. mellonella* with the activation of phenol oxidase cascade. The Bb70p can be enhancing the fungi virulence (Khan et al., 2016).

Some fungal genes have been mentioned in host colonization and killing, one of them is calcium sensor-1 (Bbcsa1) from *B. bassiana* which is homologue with a neuronal calcium-

sensor. Bbcsa1 is associated in pre-penetration or early penetration events, but is dispensable once the insect cuticle has been breached (Fan et al., 2012). For conidiation, multi-stress tolerance and virulence in *B. bassiana*, a response regulator denominated Bbssk1 is necessary. A full-length sequence of Bbssk1 is 2355 bp, encoding a 784 amino acids protein with a molecular mass of 84.5 kDa (Wang et al., 2014). Other gene expressed during colonization of insects is alcohol dehydrogenase (Adh1) from *M. anisopliae*, which is important for full capability of fungus for penetrate/colonize the insect.

MOLECULAR PHYLOGENY OF ENTOMOPATHOGENIC FUNGI AND THEIR BIOGEOGRAPHIC IMPLICATIONS

Entomopathogenic fungi constitute an important biotic component in the natural regulation of arthropod population sizes (Meyling and Eilenberg, 2007). More than 750 entomopathogenic fungal species have been isolated and described worldwide (Nielsen et al., 2008) but species of the Deuteromycete fungal genera *Metarhizium* and *Beauveria* are virulent, generalist entomopathogens that are well established as infecting a wide variety of non-social insect hosts. They are principally associated with hosts in the soil environment, and thus soil-nesting social insects, such as most ants and termites. Although these taxa are probably the most intensively studied entomopathogenic fungi, relatively little is known about their diversity in the environment. While they are known to be highly diverse across species or between widely separated populations, very few studies have looked at within population diversity (Tigano-Milani et al., 1995; Driver et al., 2000; Pantou et al., 2003).

Numerous commercial products using biological control agents (BCAs) have been developed. Most of them have used *Metarhizium* spp. (Zimmermann, 2007; Copping, 2009). Strains from the *Metarhizium* genus infect a range of insects comprising agronomically important pests such as locusts, grasshoppers, termites, noctuids, scarabid beetle larvae, spittlebugs and other hemipterans (Zimmermann, 2007). First, the classification of *Metarhizium* was based on morphological characters and was reviewed by Tulloch (1976), who only accepted *M. avoviride* and *M. anisopliae*, the latter with the short spored var. *anisopliae* and the long-spored var. *majus*. The taxonomy of *Metarhizium*, and particularly, the *M. anisopliae* morphospecies has been investigated by applying morphological, biochemical as well as genetic characteristics (Tulloch, 1976; Driver et al., 2000; Pantou et al., 2003). However, the proposed taxonomies have been incomplete and partially inconsistent. Traditional identification of *Beauveria* species is based on conidial morphology but also molecular phylogenies have revealed that the genus includes cryptic species (Rehner and Buckley, 2005).

Differentiation between inter- and intra-specific groups of entomopathogenic fungi has been possible because of molecular techniques using DNA sequences. Techniques involving polymerase chain reaction (PCR) amplification of DNA, such as RAPD (random amplified polymorphic DNA) or RFLP (restriction fragment length polymorphism), analyses of nuclear or mitochondrial DNA have been particularly useful in resolving taxonomic and evolutionary problems in fungi (Rosewich and McDonald, 1994). These tools have also led to a new phylogenetic classification of the fungi that has challenged many assumptions about the

relationships among entomopathogenic and other fungi (Blackwell et al. 2006; Hibbett et al. 2007).

The globally distributed *B. bassiana* consists of members placed in three separate clades which have been proposed to be considered separate species (Rehner and Buckley, 2005; Ghikas et al., 2010): Clade A, corresponds to *B. bassiana* and is the sister clade of Clade B, which comprises *Beauveria brongniartii* (Rehner and Buckley, 2005). The third clade, Clade C, is distantly related and includes members being morphologically indistinguishable from those of Clade A (Rehner and Buckley, 2005). Therefore, identification of *Beauveria* isolates of Clade C is only possible with the use of molecular markers. In addition, Clade A consists of an assemblage of cryptic species for which an identification system has been established designating phylogenetic species by continent and in the order of their discovery using terminology from Rehner et al., (2006) and Meyling et al., (2009). In case of Clade C, it has been reported that occurs at relatively low frequencies in a *Beauveria* community within a hedgerow habitat in Denmark (Meyling et al., 2009). Phylogenetic assignment of *Beauveria* isolates to specific clades can be done by sequencing the genomic DNA regions of the internal transcribed spacer (ITS) region of the ribosomal RNA (rRNA) gene cluster (White et al., 1990), the 5' end of Elongation Factor 1- α (EF1- α) (Bischoff et al., 2009) and the intergenic Bloc region (Rehner et al., 2006). Efficiency of these regions has been evaluated using a global collection of *Beauveria* spp, resulting that the entire EF1 region provided more phylogenetic resolution than the ITS region (Rehner and Buckley, 2005). Moreover, sequencing both EF1 α and the Bloc region of *Beauveria* isolates from a single community in an agro ecosystem in Denmark has resolved isolates among Clade A, B and C as well as identified five phylogenetic species within Clade A isolates (Meyling et al., 2009). Further molecular characterization of isolates has become possible by using molecular markers such as simple sequence repeat (SSR) in case of Clade A (Rehner and Buckley, 2003; Meyling et al., 2009) and Clade B (Enkerli et al., 2001) to assess genetic diversity of isolates from a single host species. Meyling et al., (2012) studied the genetic diversity among 32 *Beauveria* strains isolated from pollen beetles *Meligethes aeneus* collected in oilseed rape fields at different sites in Switzerland, in this study it was possible to identify three clades based on sequences of the ITS region and de 5' end of EF1- α . About half of the *Beauveria* isolates belonged to Clade C (18 of 32) indicating that it may be widespread in the investigated Swiss farmland. In fact, studies based on *Beauveria* isolates obtained from culture collections and representing worldwide distributions have revealed frequencies of *Beauveria* Clade C of 17% (Rehner and Buckley, 2005) and 22% (Ghikas et al., 2010), respectively. According to Rehner and Buckley, (2005), *Beauveria* Clade C isolates have been shown to originate from five separate insect host orders indicating a wide host range. In addition, the intergenic region Bloc provided best resolution of the clades A and B. Further genotypic diversity was revealed by simple sequence repeats (SSR) characterization of isolates within the clades except for Clade A (*B. bassiana*) which appeared to be clonal. However, the individual SSR markers were differentially amplified from isolates of the different clades, suggesting that not all available SSR markers are suitable for reliable characterization of diversity within *Beauveria* Clade C.

Phylogeny has been also assessed in *Beauveria bassiana* through analysis of genes encoding secondary metabolites that can mediate the interaction of a fungal pathogen with an insect host and help the fungus compete with other microbes. Major classes of secondary metabolites include no ribosomal peptides, alkaloids, terpenes, and polyketides, whose production appear to be controlled by various genetic and cellular regulatory mechanisms

(Punya et al., 2015). Polyketides, in particular, have been recognized as a structurally diverse family of natural products with various biological activities and pharmacological properties, which are synthesized by enzymes called polyketide synthases (PKSs). There are three types of PKSs, but fungi possess only type I PKSs and the presence of β -keto reductase (KR), dehydratase (DH) and enoyl reductase (ER) domains has led to classification of fungal PKSs into three subgroups (Cox, 2007; Chooi and Tang, 2012). Amnuaykanjanasin et al., (2009) conducted PCR employing PKS-specific degenerate primers to identify PKS genes from several fungi isolated from different habitats (insect cadavers, soil, ocean, lichen, and wood), founding a group of insect-specific PKSs classified into clade III. However, Punya et al., (2015) screened insect-specific PKS of 23 isolates of entomopathogenic fungi amplifying 72 PKS gene fragments in order to develop a more comprehensive phylogeny. Subsequent phylogenetic analysis, identified three insect-specific PKS groups in reducing clades IIa, IIb, and III which are highly conserved in entomopathogenic fungal species. PKS genes from insect-specific clades IIa and IIb were expressed only in insect-containing medium, while others were expressed only in PDB or in CYB, PDB and SDY. Also, three distinct reducing PKS clades V, VI, and VIII formed tight clusters of PKSs from various fungi with >94% NJ bootstrap support, supporting the notion that these are three new reducing PKS clades. As fungal polyketides from these entomopathogens represent valuable natural product resources, these PKSs phylogeny and expression data would be important for further studies of valuable polyketides in the future.

Metarhizium is a frequently isolated from soil environments. However, profound knowledge of natural occurrence and distribution, genetic diversity and community structure of the species is required to evaluate consequences of biocontrol initiatives (Meyling and Eilenberg, 2007). In 2009, Bischoff et al., provided a multilocus phylogeny of the *Metarhizium anisopliae* (Metschn.) Sorokin lineage and revised the taxonomy recognizing nine species within the *M. anisopliae* lineage, including several cryptic species. Given the cryptic diversity within the *M. anisopliae* lineage, discrimination of species cannot solely be based on morphology but requires the use of molecular methods for accurate identification. For species discrimination, 5' end of the elongation factor 1 α has been highlighted as a reliable marker (Bischoff et al., 2009). However, this region does not provide sufficient resolution for identification of genotypes within species. Thus, for genotyping and assessing within species diversity, simple sequence repeat (SSR) markers are currently among the most suitable markers (Enkerli and Widmer, 2010). Enkerli et al., (2005) and Oulevey et al., (2009) have developed SSR markers for strain-level genotyping within the *M. anisopliae* lineage, which have successfully been used to investigate molecular diversity of isolates collection (Velasquez et al., 2007; Oulevey et al., 2009). In 2014, Steinwender et al., evaluated *Metarhizium* community in soil from an agricultural field in Denmark using *Tenebrio molitor* as bait insect. By sequence analysis of 5' end of elongation factor 1 α and their genotypic diversity characterized by multilocus simple sequence repeat (SSR) typing, 123 isolates were identified. In this study, *Metarhizium brunneum* was most frequent (78.8%) followed by *M. robertsii* (14.6%), while *M. majus* and *M. flavoviride* were infrequent (3.3% each). It revealed co-occurrence of at four *Metarhizium* species in the soil of the same agro ecosystem with a single *M. brunneum* multilocus genotype being highly prevalent. Abundance of a single genotype could be due to variability among *Metarhizium* genotypes in response to biotic and abiotic factors prevalent in the ecosystem (Bidochka et al., 2005). Moreover, five genotypes of *M. brunneum* and six genotypes of *M. robertsii* were identified among the isolates based on SSR fragment length

analysis, demonstrating to be highly effective in detecting genotypic diversity beyond what could be found by sequencing 5' EF-1 α within the *M. anisopliae* lineage.

Additionally, the entomopathogenic hyphomycete *Paecilomyces fumosoroseus* is a promising candidate for biocontrol of the Silverleaf Whitefly *Bemisia tabaci-argentifolii* (Hemiptera: Aleyrodidae), which is considered as a major insect pest in field and greenhouse crops (Lacey et al., 1996). Since 1995, Tigano-Milani et al., demonstrated intraspecific genetic variation in this fungus by RAPD-PCR and tRNA-PCR. However, the analysis of 28S-rDNA sequences did not provide enough information for differentiation of *P. fumosoroseus* isolates. Fargues et al., (2002) investigated the genetic variability in 48 isolates of this fungus by analyzing the RFLPs and sequence data of the internal transcribed spacer sequences ribosomal RNA gene (rDNA-ITS). Digestion with six endonucleases (*AluI*, *HaeIII*, *Hin6I*, *HpaII*, *NdeII*, and *SmaI*) allowed their separation into three distinct groups. The group 1 was composed of strains isolated only from the host *B. tabaci-argentifolii*. By contrast, the group 3 included strains from various insect host and geographical origins. These data were strongly supported by phylogenetic analysis of rDNA-ITS sequence that recognized three monophyletic groups within the *P. fumosoroseus* complex. Thus, these molecular tools could be useful to assess genetic relatedness of these species into the monitoring of such biocontrol products. Genetic variations has been also suggested in *P. farinosus* according to the broad geographic and host origins and morphological variation correlated with one or more distinguishing adaptations. In the study of Chew et al., (1997) the genetic relatedness of twenty isolates of *P. farinosus* collected from seven insect species in eastern Canada was determined by RAPD analysis. All *P. farinosus* isolates were clearly distinguished from three other entomopathogenic fungi, including *P. fumosoroseus*; however, RAPD banding patterns did not correlate with ecological backgrounds or morphological phenotypes. These observations support the conclusion that *P. farinosus* from eastern Canada is not composed of strains which can be separated on the basis of the ecological or morphological criteria selected.

EVOLUTION OF PATHOGENICITY GENES IN ENTOMOPATHOGENS

Entomopathogenous fungi have developed production of different enzyme and metabolites to parasitize susceptible insect hosts, among them, hydrolytic, assimilatory, and/or detoxifying enzymes such as lipase/esterases, catalases, cytochrome P450s, proteases, and chitinases; and (b) secondary metabolites which facilitate infection (Ortiz-Urquiza and Keyhani, 2013). In *B. bassiana* bacterial-like toxins and effector-type proteins were reported (Xiao et al., 2012). Evolution of the genes codifying for these enzymes has been in a convergent way. Phylogenomic studies of different species in the *Cordyceps/Metarhizium* genera suggest that have evolved into insect pathogens independently of each other, and that their similar large secretomes and gene family expansions are due to convergent evolution (Zheng et al., 2011). Sequencing of *B. bassiana* genome confirmed that ascomycete entomopathogenicity is polyphyletic and convergent evolution to insect pathogenicity (Xiao et al., 2012).

Lipases are the first enzymes synthesized by the entomopathogenic fungi, in *Beauveria bassiana* and *Metarhizium robertsii* was reported a cytochrome P450 subfamily, these enzyme break down long-chain alkenes and fatty acids (Sanchez-Perez et al., 2014). Then, proteases

are synthesized. The catalytic function of proteases is to hydrolyze proteins releasing amino acids which could be used for fungal nutrition (Ventura-Sobrevilla et al., 2015). One of the protease produced are subtilisin type (Pr1) which are considered as virulence indicators. This type of enzyme are regulated by a signal transduction mechanism activated by the protein kinase A (PKA) mediated by AMPc (Sanchez-Perez et al., 2014). Other important group of enzyme produced by the entomopathogen fungi is chitinases which are used to break down the insect chitin.

Entomopathogens fungi descend from plant-associated fungi. Quiroz-Velasquez et al., (2014), studying the transcriptome of *Lagenidium giganteum* which is an oomycete entomopathogenic mentioned that alignments of the cellulose synthase sequence indicated that this fungus appears to be evolved from a phytopathogenic ancestor. In addition, these fungal species have retained genes indicative of plant associations, and may share similar cores of virulence factors. Members of the glycoside hydrolase family 5 subfamily 27 (GH5_27) have been proposed as putative virulence factors which may be active on the host insect cuticle, these genes are shared by different entomopathogenic fungi. These virulence factors may be very host specific with a very low risk of attacking non-target organisms or beneficial insects (Shahid et al., 2012). *Metarhizium* and *Beauveria* are also found as plant symbionts. Recent studies showed that these fungi are more closely related to grass endophytes and developed genes for insect pathogenesis while maintaining an endophytic lifestyle. Some genes for insect pathogenesis may have been co-opted from genes involved in endophytic colonization. In contrast, other genes may be multifunctional and serve in both lifestyles (Barelli et al., 2015).

Contraction and Expansion of Different Gene Families

Different entomopathogenic fungi such as *Ophiocordyceps polyrhachis-furcata*, *Beauveria bassiana*, *Metarhizium robertsii*, *Metarhizium acridum*, *Cordyceps militaris*, and *Ophiocordyceps sinensis* have similar genes implicated in pathogenicity and virulence. In *B. bassiana*, many species-specific virulence genes and gene family expansions and contractions correlate with host ranges and pathogenic strategies (Xiao et al., 2012). Contractions of some gene families in this type of fungi are implicated in narrow host-range insect species (specialists), some of these genes are cuticle-degrading genes and families of pathogen-insect interaction (PHI) genes. In some of the most specialized entomopathogens such as *O. polyrhachis-furcata*, for many genes-families has the least number of genes found (Wichadakul et al., 2015). Reduction in gene family sizes was reported in other entomopathogen (*Hirsutella thompsonii*) (Agrawal et al., 2015). The loss of different genes involved with pathogenicity result in a reduced capacity to exploit larger ranges of insect hosts and therefore in the different level of host specificity. Specialization is associated with retention of sexuality and rapid evolution of existing protein sequences (Hua et al., 2014). It is reported a co-evolution between entomopathogens and insect-host which in some case followed different patterns. Jensen et al., (2009) indicated that because of a high diversification over time among dipteran insects, the insect pathogenic fungi associated with these insects have also diversified.

On the other hand, expansions of genes involved in 1) the production of bacterial-like toxins, and 2) retrotransposable elements have been mentioned in *O. polyrhachis-furcata*, in comparison to other entomopathogenic fungi. Expansions of gene families suggest an adaptation to particular environments or sophisticated mechanisms underlying pathogenicity

through retrotransposons (Wichadakul et al., 2015). Similar pattern of evolutionary expansion of gene families such as chitinases, lipases, and proteases has been reported for *Beauveria bassiana*, *Cordyceps militaris*, and *Metarhizium anisopliae* which could be attributed to their insect killing strategies and host ranges (Agrawal et al., 2015). Generalist entomopathogens attack a wide range of insects; this condition has been associated with protein-family expansion, loss of genome-defense mechanisms, genome restructuring, horizontal gene transfer, and positive selection that accelerated after reinforcement of reproductive isolation. Generalists evolved from specialists via transitional species with intermediate host ranges and that this shift paralleled insect evolution (Hua et al., 2014). Species from the *Metarhizium* and *Beauveria* genera are recognized as generalists infecting a range of insects (Meyling et al., 2011).

Entomopathogen Fungi Pathogenicity versus Insect-Host Defense

Insects have evolved different mechanisms in response to pathogens attack, some of these mechanisms are: production of (epi) cuticular antimicrobial lipids, proteins, and metabolites; (b) shedding of the cuticle during development; and (c) behavioral-environmental adaptations (Ortiz-Urquiza et al., 2013). After 25th generations under constant selective pressure from *Beauveria bassiana*, the larvae of Greater wax moth, *Galleria mellonella*, exhibited significantly enhanced resistance, which was specific to this pathogen, and not to another insect pathogenic fungus, *Metarhizium anisopliae* (Dubovskiy et al., 2013). It was hypothesized by the same authors that insects developed a transgenerationally primed resistance which was achieved not by compromising life-history traits but rather by prioritizing and re-allocating pathogen-species-specific augmentations to integumental front-line defenses that are most likely to be encountered by invading fungi. However, there is a coevolution between entomopathogen virulence factors and host defense molecules of insects.

Virulence is thought to co evolve as a result of reciprocal selection between pathogens and their hosts. Because of shorter generation times and smaller genomes, microbes exhibit a high evolutionary adaptability in comparison with their hosts. In contrasts, insects can only compete with its pathogens if they develop mechanisms providing a comparable genetic plasticity (Vilcinskis, 2010). During *B. bassiana* infection, *Galleria mellonella* systemic immune defenses are suppressed in favor of a more limited but targeted repertoire of enhanced responses in the cuticle and epidermis of the integument (Dubovskiy et al., 2013). If a diversification of fungal proteinases for pathogenesis arose, an expansion of host proteinase inhibitors subsets contributing to insect innate immunity may occur. For example, the spectrum of proteolytic enzymes encompasses thermolysin-like metalloproteinases and this is associated with the pathogen-virulence. This spectrum putatively promoted the evolution of corresponding host inhibitors of these virulence factors (Vilcinskis, 2010). The same authors mentioned other molecular adaptations for host insect's defense such as sensing and feedback-loop regulation of microbial metalloproteinases. The genetic events behind the countermeasures in host defense effectors are gene or domain duplication and shuffling by recombination. The entomopathogens also develop different strategies in order to avoid the host insect's defenses. It has been proposed that *M. anisopliae* and *B. bassiana* survive to insect phagocytic haemocytes which are analogous to the mammalian macrophages as consequence of adaptations that have evolved in order to avoid predation by soil amoebae (Bidochka et al., 2010).

GENETIC IMPROVEMENT OF ENTOMOPATHOGENIC FUNGI FOR INSECT BIOCONTROL

Mycoinsecticides are being used for the control of many insect pests as an environmentally acceptable alternative to chemical insecticides uses (Leger et al., 1996; Hussain et al., 2014; Ortiz, et al., 2015). From 1960s, a substantial number of mycoinsecticides have been developed worldwide (Sardul et al. 2012). All groups of insects may be affected and over 700 species of fungi from around 90 genera are pathogenic to insects (Khachatourians and Sohail, 2008). Basically, the fungi pathogen activity depends on the ability of its enzymatic equipment, consisting of lipases, proteases and chitinases, which are in charge of breaking down the insect's integument (Sardul et al., 2012). Besides exoenzymes, the entomopathogenic fungi are reported to secrete toxin proteins and metabolites in vitro and sometime in vivo as well. There are a number of toxic compounds in the filtrate of entomopathogenic fungi such as small secondary metabolites, cyclic peptides and macromolecular proteins (Khan et al., 2012). To improve both commercial and technical efficiency of these entomopathogen fungi, a large number of studies had been conducting to improve their virulence which can be achieved by understanding the mechanisms of fungal pathogenesis and genetically modifying targeted genes.

In response, Fan et al., (2010) in order to accelerate penetration speed and have better target protein-chitin on the cuticle, they constructed a hybrid protease (CDEP-BmChBD) by fusion of a chitin binding domain BmChBD from *Bombyx mori* chitinase to the C-terminal of CDEP-1, a subtilisin-like protease from *B. bassiana*. After comparing studies, the hybrid protease was able to bind chitin and released greater amounts of peptides/proteins from insect cuticles. The insecticidal activity of *B. bassiana* was improved by including proteases, CDEP-1 or CDEP: BmChBD produced in *Pichia pastoris*, as an additive, however, the improved effect of CDEP: BmChBD was significantly higher than that of CDEP-1. Expression of the hybrid protease in *B. bassiana* also significantly increased fungal virulence compared to wild-type and strains overexpressing the native protease. These results demonstrated that rational design of virulence factor is a potential strategy for strain improvement by genetic engineering. Recently, a cytochrome P450 subfamily, referred as CYP52XI and MrCYP52 has been identified in *Beauveria bassiana* and *Metarhizium robertsii*, respectively (Sanchez-Perez et al., 2014). Entomopathogens such as *M. anisopliae* and *B. bassiana* are well characterized in respect to pathogenicity to several insects and have been used as myco-biocontrol agents for biological control of agriculture pests worldwide (Sardul et al., 2012).

Lenger et al., (2012) reported the development of a genetically improved entomopathogenic fungus because integration of copies from the gene encoding a regulated cuticle degrading protease (Prl) which were inserted into the genome of *M. anisopliae*. Prl was constitutively overproduced in the hemolymph of *Manduca sexta*, activating the prophenoloxidase system. The combined toxic effects of Prl and the reaction products of phenoloxidase caused larvae challenged with the engineered fungus to exhibit a 25% reduction in time of death and reduced food consumption by 40% compared to infections by the wild-type fungus. In addition, infected insects were rapidly melanized, and the resulting cadavers were poor substrates for fungal sporulation.

Fang et al., (2009) found that overexpression of a subtilisin-like protease (Pr1A) or a chitinase (Bbchit1) resulted in increased virulence of *M. anisopliae* and *B. bassiana*,

respectively. In this study, they found that a mixture of the *B. bassiana* Pr1A homolog (CDEP1) and Bbchit1 for degradation of insect cuticle were in vitro more efficient than either CDEP1 or Bbchit1 alone. Based on this, they constructed three plasmids; (1) Bbchit1, (2) CDEP1, and (3) a fusion gene of Bbchit1 linked to CDEP1 each under the control of the constitutive *gpd* promoter from *Aspergillus nidulans*. *B. bassiana* transformants secreting the fusion protein (CDEP1:Bbchit1) which penetrated the cuticle significantly faster than the wild type or transformants overexpressing either Bbchit1 or CDEP1. Compared to the wild type, the transformant overexpressing CDEP1 showed a 12.5% reduction in LT (50), without a reduction in LC (50). The LT (50) of the transformant expressing CDEP1:Bbchit1 was reduced by 24.9%. Strikingly, expression of CDEP1:Bbchit1 resulted in a 60.5% reduction in LC (50), more than twice the reduction obtained by overexpression of Bbchit1 (28.5%). This work represents a significant step towards the development of hypervirulent insect pathogens for effective pest control.

FUTURE TRENDS

It is very important to investigate more about the relation of entomopathogenic fungi to grass endophytes and how they developed genes for insect pathogenesis while maintaining an endophytic lifestyle. Although, there is known that some genes for insect pathogenesis may have been co-opted from genes involved in endophytic colonization, it is important to understand the protein changes that lead this adaptation. On the other hand, it has been mentioned that other genes may be multifunctional and serve in both lifestyles, but still there lack of knowledge about the genes modification and protein changes to have this dual activity. Advances in molecular tools for phylogeny analysis could lead to significant new insights that should allow us a better understand of the ecology of fungal entomopathogens as well as their additional roles in nature, including as plant endophytes, antagonists of plant pathogens, beneficial rhizosphere-associates and possibly even plant growth promoters.

Although some entomopathogen fungi are well known, some of the fungi of the Entomophthorales order such as *Entomophthora*, *Erynia* and *Pandora* species are poorly investigated because, the culture medium used to propagate entomopathogens such as *Beauveria*, *Metarhizium*, and *Lecanicillium*, are not the most adequate for these especial entomopathogens.

CONCLUSION

Different fungal entomopathogenic species such as *B. bassiana*, *M. acridum*, *M. anisopliae*, and *Metarhizium brunneum* have showed commercial potential for insect control, and are considered as friendly mycoinsecticide. The complete genome of some entomopathogen fungi such as *B. bassiana* has been sequenced, which has revealed multiples gene associated with virulence. In addition, many bacterial-like toxins and effector-type proteins were also discovered. Entomopathogenic fungi are able to adapt to different environments by activating well-define gene sets. During infection entomopathogenic fungi, many genes are involved in seven steps: host adhesion, germination, cuticle degradation,

growth as blastospores, host colonization and killing, immune response interactions and hyphal extrusion and conidiation.

BIOGRAPHICAL SKETCH

Name: Raúl Rodríguez-Herrera

Affiliation: School of Chemistry- Universidad Autónoma de Coahuila

Education: Agriculture minor Horticulture. 1981. Universidad Autónoma Agraria Antonio Narro. México

M. S. Plant Breeding. 1986. Universidad Autónoma Agraria Antonio Narro. México

Ph. D. Plant Breeding 1999. Texas A&M University. USA.

Post-doctorate and sabbatical training 1999, 2014. United States Department of Agriculture. USA

Address: School of Chemistry

Universidad Autónoma de Coahuila

Blvd. V. Carranza e Ing. José Cárdenas S/n

Col. Republica Saltillo Coahuila 25280 México

Research and Professional Experience:

1999-to date Full professor- Universidad Autónoma de Coahuila- México

1999 Post-doctorate training Texas A&M University-USDA USA

1997-1998 Graduate Assistant Texas A&M University-USA

1986-1998 Researcher-National Research Institute for Forestal, Agricultural and Livestock-Mexico

1982-1984 Administrator- Ministry of Agrarian Reform-Mexico

Professional Appointments:

Mexican Society of Biotechnology and Bioengineering. México

Directive Committee Symposium “Genomes and Proteomes in XXI Century.” México

Institute of Food Technologists. USA

Mexican Association of Food Science (AMECA). Mexico

Honours

1981. Graduated with honours from the UAAAN.

1988. Award to outstanding research. PCCMCA Congress. San José, Costa Rican.

1990. Award to outstanding research. PCCMCA Congress. San Salvador, El Salvador.

2001. Distinguished as National Researcher- Level 2 Mexico.

2003. National Prize on Food Science and Technology. CONACYT-Coca Cola México, D. F.

2005. Coahuila State Prize for outstanding Food Research Project. Saltillo Coahuila, Mexico.

2005. National Agro-Bio Prize on Agricultural Biotechnology-Mexico

Publications Last 3 Years:

Selected Publications (Total 216 refereed publications, 60 divulgation papers, 51 book chapters, 5 books, 6 patents, 8 bulletins, recent refereed publications are listed).

1. Meléndez Rentería, NP., Aguilar, CN., Rodríguez Herrera, R., Nevárez Moorillón, GV., 2013. Microbiological effect of fermented Mexican oregano (*Lippia berlandieri* Schauer) waste. *Waste and Biomass Valorization*. DOI 10.1007/s12649-013-9222-2
2. M. Cruz-Requena, H. De La Garza-Toledo, C. N. Aguilar-González, A. Aguilera-Carbó, H. Reyes-Valdés, M. Rutiaga and R. Rodríguez-Herrera. 2013. Chemical and molecular properties of sotol plants (*Dasyilirion cedrosanum*) of different sex and its fermentation products. *International Journal of Basic and Applied Chemical Sciences* 3 (1):. 41-49.
3. Diana B. Muñiz-Márquez, Guillermo C. Martínez-Ávila, Jorge E. Wong-Paz, Ruth Belmares-Cerda, Raúl Rodríguez-Herrera, Cristóbal N. Aguilar. 2013. Ultrasound-assisted extraction of phenolic compounds from *Laurus nobilis* L. and their antioxidant activity.” *Ultrasonics Sonochemistry* 20: 1149–1154. doi: 10.1016/j.ultsonch.2013.02.008.

ABSTRACT

We sequenced the mitochondrial (mt) *ND5* gene of 100 specimens of *Eira barbara* (Mustelidae, Carnivora). The samples represented six out of the seven putative morphological subspecies recognized for this Mustelidae species (*E. b. inserta*, *E. b. sinuensis*, *E. b. poliocephala*, *E. b. peruana*, *E. b. madeirensis*, and *E. b. barbara*) throughout Panama, Colombia, Venezuela, French Guiana, Brazil, Ecuador, Peru, Bolivia, Paraguay, and Argentina. The main results show that the genetic diversity levels for the overall samples and within each one of the aforementioned putative taxa were very high. The phylogenetic analyses showed that the ancestor of the Central and South-American *E. barbara* originated during the Miocene or Pliocene (6.3-4 millions of years ago, MYA). Furthermore, the ancestors of some geographical groups, (we detected at least four) originated during the Pliocene (3.7-2.5 MYA). These four groups (or lineages) were placed in the Cesar-Antioquia Departments (northern Colombia), Bolivia and northwestern

Argentina, northern-central Peru, and in the trans-Andean area of Ecuador. However, during the Pleistocene, this species experienced a strong population expansion and many haplotypes expanded their geographical distributions. They became superimposed on the geographical areas of older geographical groups that originally differentiated during the Pliocene. Until new molecular studies are completed, including those with nuclear markers, we proposed the existence of only two subspecies of *E. barbara* (*E. b. inserta* in southern Central America, and *E. b. barbara* for all South America). All of the demographic analyses showed a very strong population expansion for this species in the last 400,000 YA during the Pleistocene.

Keywords: Tayra, *Eira barbara*, mitochondrial *ND5* gene, putative geographical subspecies, genetic diversity, phylogeography, population expansion during the Pleistocene

INTRODUCTION

Tayra (*Eira barbara*) is a Mustelidae (Carnivora, Mammalia) with a long, and slender body. Its length varies from 56 to 71 cm, not including a 37 to 46 cm long bushy tail. Its weight ranges from 2.7 to 7 kg with males larger than females. This species has short, dark brown to black fur that is relatively uniform across the body, limbs, and tail, except for a yellow or orange spot on the chest. The fur on the head and neck is much paler, typically tan or greyish in color. The head has small, rounded, ears, long whiskers and black eyes with a blue-green shine. The feet have toes of unequal length with tips that form a strongly curved line when held together. The claws are short and curved, but strong, being adapted for climbing and running rather than digging.

This species occurs from southern Veracruz (Mexico) throughout Central America and across South America to northern Argentina save for the high Andes and the Caatinga and Cerrado (eastern Brazil; Emmons and Feer 1990). It is one of the most common medium-size predators throughout its range (Emmons and Feer 1990).

E. barbara is a diurnal, sometimes crepuscular species (González-Maya et al., 2015), with a solitary behavior and large home range (Sunquist et al., 1989). Emmons and Feer (1990) showed that the tayra inhabits tropical and subtropical forests, secondary rain forests, gallery forests, gardens, cloud forests, and dry scrub forests. Hall and Dalquest (1963) affirmed that it can live near human disturbed habitats. It frequently occurs in agricultural areas and along the edge of human settlements. Tayra usually inhabits areas below 1,200 m, but there are reports of it being in areas as high as 2,400 m (Eisenberg 1989, Emmons and Feer 1990) and it is common at 2,000 m (Cuarón et al., 2016). Its diet is omnivorous, including fruits, carrion, small vertebrates, insects, honey and small vertebrates such as marsupials, rodents, and iguanids among others (Cabrera and Yepes 1960, Hall and Dalquest 1963, Emmons and Feer 1990). This species is listed as Least Concern (Cuarón et al., 2016).

Cabrera (1957) and Hall (1981) recognized seven morphological subspecies, two in Central America and five in South-America: 1- *E. b. senex* (Thomas in 1900). The type locality is Hacienda Tortugas, Jalapa, Veracruz, Mexico; 2- *E. b. inserta* (Allen in 1908), with the type locality in Ulse, Matagalpa, Nicaragua; 3- *E. b. sinuensis* (Humboldt in 1812), with the type locality for the Sinu River in the Bolivar Department in northern Colombia; 4- *E. b. poliocephala* (Traill in 1821), with type locality Demerara in Guyana; 5- *E. b. madeirensis* (Lonnberg in 1913), with type locality in Humaitá, Madeira River, Brazilian Amazon; 6- *E. b.*

peruana (Nehring in 1886), with type locality in YuracYaku in the San Martin Department in Peru and 7- *E. b. barbara* (Linnaeus in 1758) with the type locality assigned by Lonnberg (1913) to Pernanbuco, Brazil. See Figure 1.

Although it is a relatively common species, only one preliminary study on its molecular population genetics and infra-specific systematics has been published (Ruiz-García et al., 2013).

Therefore, we expanded upon our initial molecular population genetics study with mitochondrial genes of the tayra with the following main aims: 1- To estimate the mitochondrial levels of genetic diversity in the overall tayra population and in some putative morphological subspecies; 2- To determine if there is a correlation between the molecular clades obtained in the phylogenetic analyses with the traditional putative morphological and geographical subspecies of tayras; 3- To estimate the possible temporal splits in the mitochondrial diversification within the evolution of the tayra; and 4- To determine if demographic evolutionary changes have characterized the natural history of the tayra.

MATERIALS AND METHODS

Samples

We sequenced 100 tayras at the mt *ND5* gene. The samples came from 11 countries and represent seven of the eight putative morphological subspecies (Table 1 & Figure 1). They are: 1- Argentina, eight individuals (putative *E. b. barbara*); 2- Bolivia, 16 specimens (putative *E. b. barbara*); 3- Brazil, nine exemplars (four putative *E. b. barbara*; five putative *E. b. madeirensis*); 4- Colombia, 12 individuals (three putative *E. b. madeirensis*; nine putative *E. b. sinuensis*); 5- Ecuador, 27 specimens (four putative *E. b. sinuensis*; 23 putative *E. b. madeirensis*); 6- French Guiana, five exemplars (putative *E. b. poliocephala*); 7- Panama, one individual (putative *E. b. inserta*); 8- Paraguay, four specimens (putative *E. b. barbara*); 9- Peru, 17 exemplars (nine putative *E. b. peruana*; eight putative *E. b. madeirensis*); 10- Trinidad and Tobago, one individual (putative *E. b. poliocephala*). Thus, these samples represent six out of the seven putative morphological subspecies recognized for this species.

The DNA of some of the tayra individuals we analyzed was extracted from hairs obtained from animals found alive in diverse Indian communities throughout Central and South America. Another fraction of the DNA was obtained from skins, bones, and teeth of hunted individuals of *E. barbara*. We requested permission to collect biological materials from these skins, bones, and teeth that were already present in the Indian communities. In the case of the skins, we sampled 1-2 cm². Communities were visited only once. All sample donations were voluntary, and no financial or other incentive was offered for supplying specimens for analysis. For more information about sample permissions, see the Acknowledgment section.

Figure 1. Map with the approximate geographical distributions of the six putative geographical tayra's subspecies (*Eira barbara*) sequenced at the mitochondrial *ND5* gene. X represent localities where samples were obtained.

Molecular Analyses

The DNA from skins and bones was extracted using the phenol-chloroform procedure (Sambrook et al., 1989), whereas DNA samples from hairs and teeth were extracted with 10% Chelex resin (Walsh et al., 1991). Primers and PCR conditions for the *ND5* gene (265 bp) were brought to a volume of 25 µl with 13.5 µl of Mili-Q H₂O, 3 µl of MgCl₂ 1 mM, 1 µl of dNTPs 0.2 mM, 1 µl of each primer (0.1 µM), 2.5 µl of buffer 10X, and one unity of Taq Polymerase with 50-100 ng of DNA. We used the primers L12673 and H12977 (5'-GGTGCAACTCCAAATAAAAGTA -3' and 5'-AGAATTCTATGATGGATCATGT 3'; Waits et al., 1999). The PCR temperatures were 95° for 5 minutes followed by 10 cycles of 1 minute at 95°C, 1 minute at 64°C and 1.5 minute at 72°C, 25 cycles of 1 minute at 95°C, 1 minute at 60°C and 1.5 minute at 72°C and one final extension of 15 minutes at 72°C. All amplifications, including positive and negative controls, were checked in 2% agarose gels. Those samples that amplified were purified using membrane-binding spin columns (Qiagen). The PCR products were sequenced in both directions using the Big Dye™ kit in an ABI 377A automated DNA sequencer. A consensus of the forward and reverse sequences was determined using the Sequencher program.

It is possible that some of the sequences represent numts (mitochondrial DNA fragments inserted into the nuclear genome) rather than true mtDNA (Chung and Steiper, 2008). However, we note that all amino acid translations of the obtained sequences showed the presence of initial start and terminal stop codons and the absence of premature stop codons. Protein translation was also checked to evaluate the possible presence of numts. Nevertheless, the mutations we observed were synonymous changes, thus suggesting that there were no numts in the sequences.

Data Analyses

Genetic Diversity

The statistics used to determine the genetic diversity in the overall tayra sample and within the five South American putative tayra subspecies were as follows: the haplotypic diversity (H_d), the nucleotide diversity (π), the average number of nucleotide differences (K), and the θ statistic by sequence. These statistics were obtained using the DNAsp 5.1 software (Librado and Rozas, 2009).

Phylogenetics Analyses

The sequence alignments were carried out manually as well as with the DNA Alignment program (Fluxus Technology Ltd.). MrModeltest v2.3 software (Nylander, 2004) and Mega 6.05 software (Tamura et al., 2013) were applied to determine the best evolutionary mutation model. The Akaike and Bayesian information criteria (AIC and BIC; Akaike, 1974; Schwarz, 1978) were used to determine the best evolutionary nucleotide model in the overall sequence set of *E. barbara*.

Phylogenetic trees were constructed by using two procedures: Maximum Likelihood (MLT) and Bayesian analysis (BI). The ML trees were obtained using the RAxML v.7.2.6 software (Stamatakis, 2006). To select the best fitting model, 50 independent iterations were run using three data partitions (codon 1, codon 2, and codon 3). Additionally, 50 iterations were run using two data partitions (codons 1+2 combined, and codon 3). For each sequence data set, the GTR + G model (General Time Reversible + gamma distributed rate variation among sites; Tavaré, 1986) was used to search for the ML tree and topologic support was estimated with 500 bootstrap replicates using GTR.

A BI tree was completed with the BEAST v. 1.8.1 program (Drummond et al., 2012). Four independent iterations were run using three data partitions (codon 1, codon 2, and codon 3) with six MCMC chains sampled every 10,000 generations for 30 million generations after a burn-in period of 3 million generations. We checked for convergence using Tracer v1.6 (Rambaut et al., 2013). We plotted the likelihood versus generation and estimated the effective sample size (ESS > 200) of all parameters across the four independent analyses to determine convergence and optimal results. The results from different runs were combined using LogCombiner v1.8.0 and TreeAnnotator v1.8.0 software (Rambaut and Drummond, 2013). A Yule speciation model and a relaxed molecular clock with an uncorrelated log-normal rate of distribution (Drummond et al., 2006) were used. Posterior probability values provide an assessment of the degree of support of each node on the tree. The tree was visualized in FigTree v. 1.4 software (Rambaut, 2012). This BI tree was used to estimate the time to most recent common ancestor (TMRCA) for the different nodes. We used a prior of 24.0 ± 1 MYA (95% confidence interval: 26.24–22.36 MYA) for the split between the ancestors of *Eira* and one Procyonidae, as *Potos flavus*. This prior followed the results of Koepfli et al., (2008).

Following Pennington and Dick (2010), the previous BI temporal estimates belong to one of two different approaches for inferring divergence times. The first approach is based on fossil-calibrated DNA phylogenies. The second approach is named “borrowed molecular clocks” and uses direct nucleotide substitution rates inferred from other taxa. For this second approach, we used a median joining network (MJN) with the help of Network 4.6.10 software from Fluxus Technology Ltd (Bandelt et al., 1999). The ρ statistic (Morral et al., 1994) was estimated and transformed into years of divergence among the haplotypes studied. To determine the temporal splits, it is necessary to estimate a mutation rate at the mt *ND5* gene. We used a nucleotide divergence of 1.22% per each million years (Culver et al., 2000), which yielded one mutation each 309,310 years. This estimate was obtained for Felidae. In this work, we assumed that this mutation rate could be similar in Mustelidae. The networks are more appropriate for intraspecific phylogenies than tree algorithms because they explicitly allow for the co-existence of ancestral and descendant haplotypes, whereas trees treat all sequences as terminal taxa (Posada and Crandall, 2001).

Heterogeneity Analyses

Several procedures were carried out to estimate the genetic heterogeneity among the diverse putative *tayra* subspecies analyzed. To determine the overall genetic heterogeneity in *E. barbara*, we used the statistics G_{ST} , γ_{ST} , N_{ST} and F_{ST} (Nei, 1973; Hudson et al., 1992). Additionally, we relied on the H_{ST} , K_{ST} , K_{ST}^* , Z , Z^* , and S_{nn} tests (Hudson, 2000), and the chi-square test on the haplotypic frequencies with permutation tests using 10,000 replicates to measure genetic heterogeneity. Also, we estimated the genetic heterogeneity by subspecies pairs within *E. barbara*. For this task, we used three procedures: 1- Exact tests with Markov chains, 10,000 dememorizations parameters, 20 batches, and 5,000 iterations per batch; 2- Indirect gene flow estimates (N_m) from the F_{ST} statistic with a n -dimensional island model (Slatkin, 1985; Ruiz-García, 1993, 1994, 1997, 1999; Ruiz-García and Álvarez, 2000); and 3- Kimura 2P genetic distances (Kimura, 1980). These genetic heterogeneity statistics were completed with DNAsp 5.1 (Librado and Rozas, 2009) and Arlequin 3.5.1.2 (Excoffier and Lischer, 2010).

Demographic Changes

We relied on three procedures to detect possible historical population changes in the *tayra*: 1- We used the Strobeck's S statistic (Strobeck, 1987), F_u and $L_i D^*$ and F^* tests (Fu and Li, 1993), the $F_u F_s$ statistic (Fu, 1997), the Tajima D test (Tajima, 1989) and the R_2 statistic (Ramos-Onsins and Rozas, 2002). A 95% confidence interval and probabilities were obtained with 10,000 coalescence permutations. 2- The mismatch distribution (pairwise sequence differences) was obtained following the method of Rogers and Harpending (1992) and Rogers et al., (1996). We used the raggedness rg statistic to determine the similarity between the observed and the theoretical curves. 3- A Bayesian skyline plot (BSP) was obtained by means of the BEAST v. 1.8.1 and Tracer v1.6 software. The Coalescent-Bayesian skyline option in the tree priors was selected with four steps and a piecewise-constant skyline model with 30,000,000 generations (the first 3 million discarded as burn-in), kappa with log Normal [1, 1.25] and Skyline population size with uniform [0, infinite; initial value 80]. In the Tracer v1.6, the marginal densities of temporal splits were analyzed and the Bayesian Skyline reconstruction option was selected for the trees log file. A stepwise (constant) Bayesian skyline variant was selected with the maximum time as the upper 95% high posterior density (HPD) and the trace of the root height as the treeModel.rootHeight. To determine the time range for possible demographic changes for *E. barbara*, we consider that the evolution of this taxon occurred during the last 4 MY.

RESULTS

Genetic Diversity and Phylogenetic Inferences

The BIC showed that the best nucleotide substitution model was T92 + G (7,649.51). In contrast, the AIC detected GTR + G + I (5,881.29) as the best model.

The genetic diversity levels in the overall studied sample of *tayra* were very high. For the 100 individuals analyzed, we found 70 different haplotypes with $H_d = 0.983 \pm 0.006$, $\pi = 0.0422 \pm 0.0048$ and $k = 11.175 \pm 5.117$. The genetic diversity for four out of five South American putative morphological subspecies were very similar, all of them with very high genetic

diversity levels ($H_d = 0.991-0.960$ and $\pi = 0.0562-0.0308$). The genetic diversity of *E. b. poliocephala* was somewhat lower ($H_d = 0.600$ and $\pi = 0.0176$), although the sample size for this putative subspecies was the lowest (Table 2).

The MLT and BI can be seen in Figures 2 and 3. Both phylogenetic trees showed that the first diverging branch represented the animal sampled in northcentral Panama (putatively, *E. b. inserta*) (MLT: low bootstrap 28%; BI: $p = 1$). All of the South American specimens we analyzed were placed in the remaining cluster. However, although putatively animals from five different subspecies were included, very few significant clades were observed, and only partially related to the morphological subspecies. The first diverging cluster in the South American animals was one composed by three animals from northern Colombia (Cesar and Antioquia Departments; 50% and $p = 0.97$, respectively), which corresponded with the putative *E. b. sinuensis*. Nevertheless, a Bolivian exemplar and many other specimens “a priori” classified as *E. b. sinuensis* by their geographical origins that did not belong to this cluster, were present in the BI, within this clade. Henceforth, there was only a partial correspondence between this clade and *E. b. sinuensis*. There were other interesting clades in both phylogenetic trees. 1- One was composed of three individuals from the Pacific area of trans-Andean Ecuador (61% and $p = 1$, respectively), which also partially corresponded with *E. b. sinuensis*; 2- Another cluster was composed of individuals from different areas of Bolivia and mainly by individuals from northwestern Argentina (Salta, Jujuy and Tucuman provinces) in MLT (41%). In the BI, this group was only composed of five individuals from northwestern Argentina ($p = 0.96$). This cluster was partially correlated with *E. b. barbara*. In the BI there was another cluster with several Bolivian and Argentinian specimens ($p = 0.84$). **It was separated from the first Argentinian cluster we aforementioned.** However, as we commented for *E. b. sinuensis*, this relationship was incomplete because other individuals “a priori” classified as *E. b. barbara* were dispersed by other clusters; 3- Another cluster of certain relevance was detected in the MLT and BI. It was composed of individuals of central Peru and one individual from the northern Peruvian Amazon (80% and $p = 0.72$, respectively). This cluster also partially supported the existence of the morphological subspecies *E. b. peruana*; 4- Small clusters of animals from the Ecuadorian and Colombian Amazon were present. One of them contained two animals from the Ecuadorian and Colombian Amazon (62% and $p = 1$, respectively) and other three from the Ecuadorian Amazon (73% and $p = 1$; 89% and $p = 1$; 28% and $p = 0.8$, respectively). These very locally restricted clusters were inside the putative morphological subspecies, *E. b. madeirensis*. Many other individuals of *E. b. madeirensis* were distributed in clusters with other individuals “a priori” considered different morphological subspecies.

Table 2. Genetic diversity in the overall sample of *Eira barbara* and in the five putative South American morphological subspecies at the mt ND5 gene represented by the number of haplotypes (NH), the haplotype diversity (H_d), the nucleotide diversity (π), and the average number of nucleotide differences (K)

<i>Eira barbara</i> taxa	NH	H_d	π	K
Overall Sample	70	0.983 ± 0.006	0.0422 ± 0.0048	11.175 ± 5.117
<i>E. b. sinuensis</i>	12	0.987 ± 0.065	0.0562 ± 0.0311	14.884 ± 8.344
<i>E. b. poliocephala</i>	14	0.600 ± 0.147	0.0176 ± 0.0093	4.667 ± 2.556
<i>E. b. peruana</i>	13	0.989 ± 0.063	0.0517 ± 0.0299	13.703 ± 7.324
<i>E. b. madeirensis</i>	26	0.960 ± 0.009	0.0308 ± 0.0071	8.162 ± 3.233
<i>E. b. barbara</i>	25	0.991 ± 0.012	0.0412 ± 0.0092	10.928 ± 4.111

Figure 2. (Continued).

Figure 2. (Continued).

Figure 2. Maximum likelihood tree with the 100 specimens of tayra (*Eira barbara*) sequenced at the mitochondrial *ND5* gene. The number in the nodes are the bootstrap percentages. The procyonidae, *Potos flavus*, was employed as outgroup. In different colors, some relevant clusters which showed a limited correspondence with some putative morphological geographic subspecies of *E. barbara*.

Figure 3. (Continued).

Figure 3. (Continued).

Figure 3. Bayesian tree with the 100 specimens of *tayra* (*Eira barbara*) sequenced at the mitochondrial *ND5* gene. The three numbers in the nodes are the posteriori probabilities, estimated temporal splits in the nodes in millions of years, and the 95% high posterior density of these temporal splits. The *Procyonidae*, *Potos flavus*, was employed as outgroup. In different colors, some relevant clusters which showed a limited correspondence with some putative morphological geographic subspecies of *E. barbara*.

The BI temporal split estimate showed an initial divergence of the ancestors of the Panamanian individual (*E. b. inserta*) and South-American specimens around 6.26 MYA (95%: 5.4-8.49 MYA; Miocene divergence). The ancestor of the clade from northern Colombia split around 3.7 MYA (1.55-6.37 MYA). The ancestor of the animals from northwestern Argentina diverged around 3.15 MYA (1.01-4.23 MYA). In contrast, the ancestors of animals of north-central Peru, trans-Andean Ecuador and one of the Ecuadorian Amazonas clusters diverged 2.88 MYA (1.23-4.2 MYA), 2.35 MYA (0.31-2.7 MYA), and 1.49 MYA (0.42-3.74 MYA), respectively.

Figure 4. Median Joining Network (MJN) for the haplotypes detected in 100 tayra (*Eira barbara*) sequenced at the mitochondrial *ND5* gene. In light blue, one haplotype of *E. b. inserta*; in pink, haplotypes of *E. b. barbara*; in green, haplotypes of *E. b. peruana*; in yellow, haplotypes of *E. b. madeirensis*; in black, haplotypes of *E. b. sinuensis*; and in brown, haplotypes of *E. b. poliocephala*. Therefore, the five putative geographical subspecies of South American tayras and one Central America subspecies were represented in this analysis. Little red circles are extinct or not found haplotypes.

The MJN analysis revealed a view very similar to the phylogenetic trees (Figure 4). The major fraction of haplotypes were distributed irrespective of the geographical distribution of the morphological subspecies. For instance, the most frequent haplotypes (H1, H30, H7, H49, H19 and H9) included individuals of different putative subspecies: H1 contained exemplars classified “a priori” as *madeirensis*, *sinuensis* and *barbara*; H30 and H7 were composed of *madeirensis* and *peruana* individuals; H49 enclosed individuals of *sinuensis*; H19 consisted of specimens of *sinuensis*, *peruana*, *madeirensis*, and *barbara*, whilst H9 included *poliocephala* and *peruana*. Therefore, some haplotypes were widely distributed, which agrees quite well with extensive gene flow of this species across all of South America. Many of these main haplotypes presented other small haplotypes in star-like form, which is highly related to possible population expansions across the entire South American range of the tayra. Nevertheless, the MJN, as the phylogenetic trees, detected some haplotype clusters to be well delimited geographically. For example, there were the cases of the Central American individual (H66),

the Cesar-Antioquia cluster (H65, H67, and H68), the trans-Andean Ecuadorian cluster (H45, H63, and H64), and the central Peruvian cluster (H11, H13, H18, and H20). The MJN temporal splits were slightly less than that those obtained with BI, but relatively similar. The temporal splits among these haplotypes and the main groups can be seen in Table 3. Some of these time splits are interesting. The divergence between the Panamanian individual and H7 was estimated to occur around 4.02 ± 0.31 MYA. The temporal divergence between clusters from the areas of northwestern Argentina, Cesar-Antioquia area (northern Colombia), trans-Andean Ecuador, and north-central Peru in reference to H7 were 3.73 ± 0.65 MYA, 3.29 ± 0.57 , 1.04 ± 0.31 MYA, and 2.89 ± 0.47 MYA, respectively.

Therefore, the phylogenetics tree and the MJN analyses showed that the ancestor of Central and South American tayras originated during the Miocene or Pliocene. Also, the ancestors of some geographical groups, at least four of certain relevance, originated during the Pliocene and first part of the Pleistocene. However, during the Pleistocene (as we will show later), tayra experienced a strong population expansion and many haplotypes expanded their geographical distributions. They superimposed onto the geographical areas of these older and geographical groups that originally differentiated during the Pliocene.

Genetic Distances and Genetic Heterogeneity among Putative Morphological Subspecies of *Eira barbara*

The Kimura 2P genetic distances among all of the comparison pairs of the six putative morphological subspecies of tayra are shown in Table 4. The differentiation between the Central American subspecies (*E. b. inserta*) and the five South American subspecies was elevated (5.5% - 7.8%), which confirmed that the Central America taxon is, at least, a different subspecies. It is interesting to note that the less differentiated South American taxon with regard to the Central American one was *E. b. sinuensis* (5.5%). It was the South American taxon closest geographically. The genetic distances with the other four South American taxa ranged from 7.1%-7.8%.

In contrast, the genetic distances among the five South American subspecies were very small. They ranged from 0.1% to 1.2%. The pairs of subspecies with the greatest genetic distances were *E. b. poliocephala*-*E. b. sinuensis* (1.2%) and *E. b. poliocephala*-*E. b. barbara* (0.9%).

The overall genetic heterogeneity for all five South American tayra subspecies taken together was significant (Table 5), but the genetic heterogeneity was relatively small. For example, the F_{ST} and the γ_{ST} statistics showed values of 0.095 and 0.109, respectively. Their respective gene flow estimates of 4.75 and 4.10, were relatively high among the putative South-American subspecies.

The analysis of subspecies pair comparisons with exact probability tests (Table 6) only showed two significant pairs: *E. b. madereinsis*-*E. b. barbara* ($p = 0.0066 \pm 0.0017$) and *E. b. madereinsis*-*E. b. poliocephala* ($p = 0.0135 \pm 0.0034$). In this analysis, the Central American taxon was deleted because only one sequence was analyzed. The estimates of N_m by subspecies pair comparisons (Table 7) clearly yielded that the values lower than 1 (which is considered the limit for low gene flow; Wright, 1943) always implied the Central American taxon: *E. b. inserta*-*E. b. peruana* ($N_m = 0.584$), *E. b. inserta*-*E. b. barbara* ($N_m = 0.459$), *E. b. inserta*-*E.*

b. madereinsis ($N_m = 0.286$), *E. b. inserta*-*E. b. poliocephala* ($N_m = 0.137$). Only a South American taxon, *E. b. sinuensis*, ($N_m = 1.202$) had a more substantial gene flow with *E. b. inserta*. This agrees quite well with that determined in the phylogenetic trees and in the genetic distance analysis. The gene flow estimates among the South American taxa were all above 1, ranging from 2.469 to 11.847. These values strongly correlate to elevated historical gene flows among the populations of tayra throughout South America.

Table 3. Temporal splits among different *Eira barbara*'s lineages estimated by means of a Median Joining Network (MJN). Values of temporal splits are in millions of years. SD = Standard deviation

Figure 5. Historical demographic analysis by means of the mismatch distribution procedure (pairwise sequence differences) for the mitochondrial *ND5* gene studied in the overall sample of *Eira barbara*. The analysis showed a clear population expansion of this species during the Pleistocene.

The mismatch distributions also indicated population expansion ($rg = 0.0040$, $P = 0.00280$) (Figure 5). Assuming one year as one generation in the tayra, the population expansion began 343,586 YA, during the Pleistocene.

The BSP analyses also determined a strong female population expansion during the Pleistocene for the tayra (Figure 6). The analyses showed the beginning of the expansion around 400,000 YA, very similar to the temporal estimate previously showed. Therefore, there is incontrovertible evidence that the tayra experienced a strong population expansion during the Pleistocene, as was previously suggested by the MJN analysis.

Figure 6. Bayesian skyline plot analysis (BSP) to determine possible demographic changes across the natural history of the overall sample of tayra (*E. barbara*) sequenced at the mitochondrial *ND5* gene. The analysis showed a clear female population expansion during the Pleistocene. On the x-axis, time in millions of years; on the y-axis, log effective population size of females.

DISCUSSION

Genetic Diversity

The levels of nucleotide diversity found in *E. barbara* ($\pi = 0.0422$) were quite high. They were higher than those found in many other neotropical carnivores. For example, they were higher than three fox species (*Lycalopex culpaeus*: $\pi = 0.008$, Ruiz-García et al., 2013a; *Lycalopex sechurae*: $\pi = 0.015$, Ruiz-García et al., 2013a; *Cerdocyon thous*: $\pi = 0.019$, Tchaika et al., 2006), three otter species (*Lontra felina*: $\pi = 0.005$, Vianna et al., 2010; *Lontra longicaudis*: $\pi = 0.011$, Ruiz-García et al., 2017a; *Pteronura brasiliensis*: $\pi = 0.0086$, Ruiz-García et al., 2017a), and two vulnerable Neotropical cats (*Leopardus jacobita*: $\pi = 0.0047$, Ruiz-García et al., 2013b; *Leopardus guigna*: $\pi = 0.00461$, Napolitano et al., 2013). The values of *E. barbara* were similar to those found in certain Neotropical cats, which are characterized by very elevated genetic diversity levels (*Puma yaguaroundi*: $\pi = 0.0661$; Ruiz-García and Pinedo-Castro, 2013 and Ruiz-García et al., 2017b; *Leopardus pajeros*: $\pi = 0.0513$, Ruiz-García et al., 2013b; *Leopardus pardalis*: $\pi = 0.068$, Eizirik et al., 1998; *Leopardus wiedii*: $\pi = 0.035$ - 0.074 , Ruiz-García et al., 2017c).

These high levels of genetic diversity in “a priori” neutral markers, as that we studied, could be related with the fact that many other genes in the genome of a given species contains enough variability for the action of natural selection (Kimura, 1986). This could be the origin of the great morphological variation and behavior plasticity found in the tayra. Emmons and Freer (1990) determined that tayras could live in a wide variety of habitats such as tropical and subtropical forests, primary rain forest (as throughout the Amazonian forest in Brazil, Peru,

Colombia and Ecuador), secondary rain and gallery forests (as in the Llanos of Venezuela and Colombia), gardens, plantations, and cloud forests. They also inhabit dry scrub and deciduous forests (as in the Pantanal in Brazil, Paraguay and Bolivia) and tall grass savannas (as in Argentina, Bolivia, and Paraguay). Sunquist et al., (1989) showed that the extreme plasticity of this species for habitat preferences, activity periods, and diet preferences may reduce interspecific competition between *E. barbara* and other carnivores. This could also be the explanation why Konecny (1989) found no significant habitat preference for this mustelid in Belize. The abundance of the tayra throughout much of Central and South America may be a consequence of its ecological flexibility compared to sympatric carnivores. Associated with this, the tayra is a generalist predator, consuming a variety of fruits, carrion, small and medium vertebrates, insects, and honey (Cabrera and Yepes, 1960; Galef et al., 1976; Hall and Dalquest, 1963; Konecny, 1989; Sunquist et al., 1989).

Genetic Heterogeneity, Gene Flow and the Systematics of the Tayra

Our results clearly showed that the specimen sampled in Central America was highly divergent from all of the individuals sampled in South America. However, the genetic heterogeneity among the putative morphological subspecies of South American tayras, although significant, is very small as we found with the F_{ST} statistic, exact probability tests, and genetic distances. The indirect gene flow estimates were clearly higher than 1. Wright (1943) stated that in an island model, if $Nm > 1$, then gene flow is important enough to erase the genetic heterogeneity among populations. In a stepping-stone model, this amount must be larger than 4 (Trexler, 1988). In both models, $Nm < 0.5$ means that the populations are highly disconnected from a reproductive point of view. For instance, the gene flow estimates between *E. b. inserta* and *E. b. poliocephala* ($Nm = 0.137$), *E. b. inserta* and *E. b. madereinsis* ($Nm = 0.286$) and *E. b. inserta* and *E. b. peruana* ($Nm = 0.459$) showed that the Central American taxon is completely isolated from these three South American taxa. However, recall that certain genetic relatedness was detected between the Central American taxon and the most northern South American taxon (*E. b. sinuensis*). Additionally, we found several gene flow comparison pairs between South American taxa, such as *E. b. madereinsis*-*E. b. barbara* ($Nm = 9.289$) and *E. b. madereinsis*-*E. b. poliocephala* ($Nm = 2.168$). They were elevated, although these comparison pairs showed significant heterogeneity. This might be explained according to Alledorf and Phelps (1981), who argued that the most correct interpretation of $Nm > 1$ is that the populations share the same alleles, although not necessarily with the same allele frequencies. By means of simulations, these authors showed that significant allele divergence occurred in 50% of the generations with a gene flow of $Nm = 50$. Significant allele divergence happened on most occasions when $Nm = 10$.

The tayra seems to have a strong dispersion capacity, which could be related with these high gene flow estimates detected for all the putative South American subspecies. For instance, in the Venezuelan and Colombian Llanos, tayras are usually found along gallery forests. However, tayras cross these extensive grasslands at night, presumably moving from one forest to another covering long distances (Defler, 1980).

Taking into consideration all these facts, we suggest that the six putative morphological subspecies analyzed could be reduced to two different subspecies: *E. b. inserta* for southern Central America and *E. b. barbara* for all South America. The name should be *E. b. barbara*

because it was given by Linneus in 1758 versus *E. b. sinuensis* given by Humboldt in 1812, *E. b. peruana* given by Nehring in 1886, *E. b. madeirensis* given by Lonnberg in 1913 and *E. b. poliocephala* given by Traill in 1821. In reference to the putative northern Central America subspecies (*E. b. senex*), we cannot add any comment on its systematics because no individual of this putative subspecies was analyzed. Therefore, it is essential to sample tayras from this putative subspecies to determine its relationships with other tayra taxa.

Here we suggest another alternative point of view. As we showed, the first tayra's splits originated during the Miocene-Pliocene and beginning of the Pleistocene. However, during the Pleistocene, tayra experienced a strong population expansion and many haplotypes expanded their geographical distributions and they became superimposed on the geographical areas of older geographical groups that originally differentiated during the Pliocene. We suggest that future studies analyze nuclear genes to determine if there was hybridization between the older geographical groups (northern Colombia, part of Bolivia and northwestern Argentina, trans-Andean area of Ecuador, and north-central Peru) and the tayra's population that expanded throughout South America during the Pleistocene. If data support this, then our view of a unique tayra's subspecies in South America should be valid. On the contrary, if there was little or no hybridization between the original groups and Pleistocene colonizers in sympatry, then the number of subspecies in South America could be higher. Therefore, the northern Colombian population (Cesar, Antioquia and possibly nearby areas) should be named *E. b. sinuensis* and the northern central Peruvian population should be named *E. b. peruana*. Also, the Bolivian and especially the northwestern Argentinian population should be defined as a new subspecies (tentatively *E. b. saltensis*). The trans-Andean Ecuadorian population should be defined as a new subspecies (tentatively *E. b. aequatorialis*). The remaining populations of tayra in South America should be named as *E. b. barbara*. Additionally, the range distribution of *E. b. sinuensis* and *E. b. peruana* should be more restricted than traditionally accepted (see Presley, 2000). Even, if some reproductive isolation mechanism had emerged between the Central and the South America tayras due to the old split estimated during the Miocene-Pliocene, both tayra populations should be consider two different species (*E. barbara* and *E. inserta*; this last should be *E. senex* if both Central American forms of tayra were genetically undifferentiated because *senex* was firstly named by Thomas in 1900 and *inserta* was named by Allen in 1908).

Only future nuclear genetic studies can clarify which of the two points of view is more acceptable.

Temporal Splits in the Tayras

Our results showed that the divergence between the Central and the South American tayras occurred around 6.3 to 4 MYA (Miocene or Pliocene periods depending of the temporal estimation). Johnson and O'Brien (1997) and Johnson et al., (2006) showed that seven of the eight primary lineages of felids radiated in the early part of the Late Miocene (10.8-6.2 MYA). There was a noteworthy cooling of the global climate near the end of the Middle Miocene. This period of cooling coincides with formation of a permanent Antarctic ice sheet in the Middle and in the Late Miocene and an Arctic ice sheet in the Pliocene. A large peak of diversification in many vertebrate taxa occurred during the Pliocene epoch. The cold and dry climate during the Pliocene, coincides with the onset of high latitude glacial cycles, causing an explosive expansion of low-biomass vegetation, including grasslands and steppe at mid-latitudes and

development of taiga at high latitudes of Eurasia and North America. These changes were correlated with the diversification of prey species such as muroid rodents and passerine birds that exploited these new habitats, which in turn provided new niches for little or medium carnivores, such as the tayra. Additionally, this Pliocene period agrees quite well with the last phase of rising of the Andes as shown by Dollfus (1974) and Clapperton (1993) (see, for instance, the rising of the “tablazos” of Piura, Peru) and very high volcanic activity in the Andes, with replacement of rainforests with steppe and grassland environments.

Our initial divergence estimates in the tayra agrees relatively well with other molecular studies in the reconstruction of the phylogenetic relationships in the Mustelidae (Bryant et al., 1993; Dragoo and Honeycutt, 1997; Koepfli and Wayne, 1998, 2003; Sato et al., 2003, 2004; Flynn et al., 2005; Fulton and Strobeck, 2006; Koepfli et al., 2008). Two molecular studies are fundamental to understanding the phylogenetics of the Mustelidae (Koepfli and Wayne, 2003; Koepfli et al., 2008). In the first study, the authors used five nuclear gene segments and the mt *Cyt-b* gene. The genes *APOB*, *FES*, *GHR*, *RH01* and *mtCyt-b* clustered *E. barbara* together with *Martes americana*, *Martes pennanti* and *Gulo gulo*. On the other hand, *CHRNA1* clustered *E. barbara* with *Meles meles* and *Arctonyx collaris*. The major part of the trees generated by these authors showed that Mustelinae and Melinae were polyphyletic within the Mustelidae, whereas Lutrinae was monophyletic. The authors of the second study analyzed 22 nuclear and mitochondrial gene segments and determined Mustelidae to consist of seven primary groups. These groups include four major clades and three monotypic lineages. It also included *Eira barbara* clustered into the subfamily Martinae, together with *Martes* and *Gulo*, the most divergent taxa within this subfamily (100% of bootstrap and posterior probability of 1). In that study, the branch of *E. barbara* diverged from the other Mustelidae around 6.7-7.7 MYA (calculated using the mean values), which agrees with our estimate.

These molecular results are not in conflict with the fossil record we know and understand for Mustelidae in America. Many species of Mustelidae appeared in North America during the Late Miocene-Early Pliocene. For instance, *Cernictis hesperus*, from the Pinole Tuff Local Fauna of California, has been dated radiometrically to have lived 5.3-5.5 MYA (Tedford et al., 2004; Baskin, 2011). Other cases of extinct genera appearances are *Trogonictis* and *Sminthosinis* as well as extant genera such as *Lutra* and *Mustela* during the Hemphillian period (4.7-5.9 MYA, Tedford et al., 2004). There is also *Legionarictis fortidens* from the Barstovian (Middle Miocene) marine Temblor Formation in California (Tseng et al., 2009). This form has shown a very close resemblance to other Miocene Mustelidae genera such as *Dehmictis*, *Eirictis*, *Iberictis*, and *Trochictis*, all from the Old World. The form also closely resembles *Sminthosinis*, *Trigonictis* (all from the New World), and, especially, with two extant genera, *Galictis* and *Eira* (Ray et al., 1981; Ginsburg and Morales, 1992; Baskin, 1998; Ginsburg, 1999). In fact, the cladistic analysis of Tseng et al., (2009) determined that this genus could be an evolutionary basal stage closely related to *Eira*. At the Longdan Fauna of the Gansu Province in China, a similar fossil to *Eira* was found by Qiu et al., (2004) from the Late Pliocene (*Eirictis robusta*; 2.58-2.15 MYA). However, the cladistic analysis of Tseng et al., (2009) determined that this mustelid was not very close to *Eira* and it is probably younger than *Eira*. Two possible fossil species of *Eira* have been described from post-Pliocene deposits of Maryland and Virginia under the names *Galera macrodon* and *G. perdicida*. However, the former has been assigned to *Trigonictis* based on additional material collected from deposits of the Blancan land mammal age from Washington, Idaho, Nebraska, Kansas, Texas, North Carolina, and Florida (Ray et al., 1981). *Trigonictis* is considered an intermediate form between *Galictis* and *Eira*

and could be ancestral to both. The second species may be *Mephitis* (Alston, 1882). In addition, extinct species of *Eira* were noted from the Pliocene of the Eastern Hemisphere, but specific names were not given (Scott, 1937). Hershkovitz, (1972) claimed that *Eira* and other endemic monotypic mustelid genera, such as *Lyncodon* and *Pteronura*, may have evolved in South America and moved north as part of the north and south American interchange across the Panamanian land bridge. In contrast, fossil records suggest that *Eira* may have a North American origin (Ray et al., 1981).

Therefore, the process of diversification within *Eira* could be at the end of the first mustelid diversification peak or at the beginning of the second mustelid diversification peak detected by Koepfli et al., (2008). In either case, this mitochondrial diversification process occurred before the Panamanian land bridge (3-2.5 MYA). Therefore, *Eira*'s could have radiated in North America before South America in concordance with the fossil record (Ray et al., 1981) and against the view of Hershkovitz (1972). If so, tayras arrived in South America before the complete formation of the Panamanian land bridge, coinciding with the Choco-Panama island bridge (Galvis, 1980), which could have been used by the ancestors of the current *E. barbara* to colonize northern South America from Central America. During the upper Pliocene orogeny, the present Tuira, Atrato and Sinu river basins and the nearby lowlands were raised above sea level. Thus, the mountains of southern Central America and of the northern Andes were uplifted to about their present elevation (Van der Hammen, 1961). Although the Nicaraguan, Panamanian and Colombian portals remained open (upper Miocene-middle Pliocene), numerous volcanic islands existed from the lower Atrato Valley and the Tuira River Basin of eastern Panama to the Nicaraguan portal. They could have been used by *Eira*'s ancestor to migrate southward. The Cuchillo Bridge of the Uraba region, connecting the Tertiary Western Colombian Andes with the Panamanian islands was probably above sea level during this period. Henceforth, tayras could be another "island hopper" species (Simpson 1950, 1965, 1980).

Our results could also be considered as indirect evidence of a Miocene origin of the Isthmus of Panama (Montes et al., 2012, 2015). Indeed, the Isthmus of Panama formation began earlier and seems to be associated with the Northern Andean uplift, around 24 MYA (Farris et al., 2011).

Therefore, the tayra could have arrived in South America before other Mustelidae. Koepfli et al., (2008) claimed that genera and species of mustelids found in South America today are largely descended from North American immigrants that arrived as part of the GABI following the rise of the Panamanian isthmus, 3.0-2.5 MYA. Several informational points support the statement of Koepfli et al., (2008). 1-For example, there is the clade of New World otters where *Lutra canadensis* is sister to *Lontra felina*, and *Lontra longicaudis*. The latter two species are found in South America and are estimated to have diverged 2.8–3.4 MYA (95% HPD: 1.6–5.2 MYA) overlapping with the formation of the Panamanian land bridge. 2-The long-tailed weasel, *Mustela frenata*, ranges from North America to northern South America. In addition, *Mustela africana* and *Mustela felipei* are endemic to South America. Fossil evidence clearly indicates that *Mustela* colonized South America from the north, apparently well after the Panamanian isthmus was in place. 3- Fossils of the current *Lyncodon patagonicus*, (and a fossil form very related as *Lycodon bosei*) and *Stipanicia* sp (closely related to the extant *Galictis cuja*) have been registered in the Ensenadean and Bonaerense periods of the Argentinian Pleistocene (Forasiepi et al., 2007). However our results could be ratified by other results provided by the same authors (Koepfli et al., 2008). They found that *Pteronura*, *Galictis* and *Eira* could have a Eurasian origin for each genus with posterior diversification in North

America. For example, *Pteronura* may be related to the extinct genus *Satherium* from the Pliocene of North America. Additionally, *Eira* may be related to *Trigonictis* and *Legionarictis*, also North American fossils (Tseng et al., 2009). Fossil evidence suggests mustelids colonized the New World across Beringia during different intervals when the land bridge between Eurasia and North America was open. Multiple genera of mustelids migrated into North America during the Late Miocene (around 11.2–5.3 MYA), prior to the first opening of the Bering Strait 5.4–5.5 MYA, which severed the route across Beringia. Many genera that colonized North America during the Late Miocene or earliest Pliocene became extinct. However, *Eira* could be one of the surviving genera that began to diversify in North America and also in South America if we accept that they arrived in South America before the complete formation of the Panamanian land bridge.

The mitochondrial diversification of the oldest groups of South American tayra occurred 3.7–2.3 MYA. This coincided with the climatic changes that originated from the completion of the Panamanian land bridge (3.1–2.8 MYA; Marshall et al., 1979, 1982; Marshall, 1985, 1988; Webb, 1985, 1997; Coates and Obando, 1996) in the Last Pliocene. Diversification in the tayra occurred close to the Gelasian period (2.5–1.8 MYA), a period characterized by the last stages of a global cooling trend that led to the quaternary ice ages (International Commission on Stratigraphy 2007). Around 2.5 MYA, the Andean forests were transformed into open cold dry savannah ('paramo'), which could have potentially isolated populations of different species. They could have crossed the Northern Andes coming from Central America. Van der Hammen (1992) demonstrated that the mean temperature in the Colombian Andes was 4 °C lower than today. He also stated that the rain level descended below the level reported for today (500–1,000 mm). At 2,500 meters above sea level (masl), the temperature was 10 °C lower than it is today. Tayra's diversification could have been affected by the rapid uplift that resulted in a significant elevation of the Northern Andes. The mountain range's height climaxed around 2.7 MYA when the northern Colombian Andes reached its present day elevation (Gregory-Wodzicki, 2000). This also coincides with the last formation of the Central Andes. All of the Andean chain between Cajamarca and Huancavelica in Peru appeared by volcanism in this period.

Much of the mitochondrial diversification process of the typical Pleistocene colonizer haplotypes occurred around 1.5–0.8 MYA. This divergence could have been initiated by the pre-Pastonian glacial period (1.3–0.8 MYA), which had the highest glacial peak of the first Quaternary glacial period (Günz). This glacial period was extremely dry, and there was a great degree of forest fragmentation. This period was a time for haplotype diversification. It was also a time of separation for many carnivores as it was previously determined for the Pampas cat (Cossíos et al. 2009), and for the foxes of the *Lycalopex* genus (Ruiz-García et al. 2013a). Around 1.3 MYA, the Buenos Aires's fauna transformed into a typical semi-arid Patagonian fauna, represented by the guanaco, *Lestodelphys* and *Lyncodon*. Therefore, the climate was considerably colder and drier than today and could have influenced the mitochondrial fragmentation within the tayra.

The strong population expansion detected around 0.4 MYA for the tayra agrees well with an interglacial period (0.39–0.20 MYA, West 1967) characterized by higher temperatures and humidity and forest expansions (Hoxniense in the British Islands, Yarmouth in North America, Holstein in northern Europe and Mindel-Riss interglacial period in central Europe).

Future analyses with nuclear markers are needed as well as samples from Central America (especially, southern Mexico, Guatemala, Belize and Honduras), the Pacific areas of Colombia

and Ecuador, other areas of Central Peru, and the Guyana shield. These markers and additional samples will help us to determine the exact number of subspecies or ESUs (Moritz, 1994). This information is crucial for the development of effective conservation plans for this species.

ACKNOWLEDGMENTS

Special thanks to Dr. Diana Álvarez, Dr. Francois Catzeflis, Pablo Escobar-Armel, and Lina Arguello for their help in obtaining samples of tayras throughout Panama, Colombia, Trinidad, French Guiana, Peru, Ecuador, Brazil, Bolivia, Paraguay and Argentina. Thanks also go to the Instituto von Humboldt (Colombia), the Ministry of Environment, Consejo Nacional del Ambiente and the Instituto Nacional de Recursos Naturales in Peru, to the Colección Boliviana de Fauna (Dr. Julieta Vargas), to CITES in Bolivia and to the Ministerio del Ambiente in Coca and Santo Domingo de Tsáchilas (Ecuador) for their role in facilitating the obtainment of the collection permits in Colombia, Peru, Bolivia and Ecuador. Also thanks go to the Panamanian and Argentinian Ministries of Environment for their roles in obtaining permissions in these countries. Additional thanks to the many people of the diverse Indian tribes in Peru (Bora, Ocaina, Shipigo-Comibo, Capanahua, Angoteros, Orejón, Cocama, Kishuarana, and Alamas), Colombia (Jaguas, Ticunas, Huitoto, Cocama, Tucano, Nonuya, Yuri, Yucuna, Curripacos, and Desano), and Ecuador (Kichwa, Huaorani, Shuar, and Achuar) for their help in obtaining tayra samples.

Chapter 69

THE PRECISION MEDICINE AND PRECISION PUBLIC HEALTH APPROACHES TO CANCER TREATMENT AND PREVENTION: A CROSS-COMPARISON

Stephen M. Modell^{1,*}, Sharon L. R. Kardia² and Toby Citrin¹

²Department of Epidemiology

University of Michigan School of Public Health, Ann Arbor, MI, US

ABSTRACT

Like other forms of diagnostics, genetic testing comes with a retinue of costs and benefits. Significant benefits in terms of morbidity and mortality have accrued to individuals tested for more prevalent genetic conditions like cystic fibrosis and sickle cell disease, including persons seen in the emergency room or identified through public health surveillance. These benefits do not mitigate the drawbacks of genetic testing, false and missed diagnoses and sheer cost among them.

Both medicine and public health have aimed at means of maximizing genetic test benefits in the interventions that they apply. The President's Precision Medicine Initiative (PMI) holds promise in that its results could be used to tailor medical treatments to the individual characteristics of patients, "precision" implying a more accurate and precise regimen overall. The National Cancer Institute (NCI) has already launched the NCI-MATCH precision medicine trial, which assigns targeted treatments based on the genetic abnormalities in a tumor, regardless of cancer type. Other trials, such as the NCI Pediatric MATCH trial, are yet to happen. The efficacy of cancer treatments also intersects public health concerns. The Evaluation of Genomic Applications in Practice and Prevention (EGAPP) Working Group has evaluated the use of *UGT1A1* genotyping to determine the best dose of irinotecan to prevent side effects when treating patients for metastatic colorectal cancer. Analytic validity does not always equate with improved patient

outcomes, however, thus the public health emphasis on development of a suitable evidence base for precision medical and public health efforts.

The public health approach to precision medicine, or “precision public health”, differs from the medical approach in several important ways: (1) population-based with attention to at-risk populations, as opposed to being strictly individualized; (2) focus on primary and secondary prevention, rather than frank disease (tertiary prevention); and (3) prioritizing interventions that have already demonstrated readiness for large-scale implementation, in contrast to the undertaking of novel clinical trials. Precision public health is exemplified in the Centers for Disease Control and Prevention’s emphasis on the implementation of Tier 1 genetic tests that have passed systematic review for analytic and clinical validity and utility – the use of family history for referral for hereditary breast and ovarian cancer genetic testing (*BRCA1/2* mutations), and hereditary nonpolyposis colorectal cancer cascade screening (Lynch syndrome *MLH1*, *MSH2*, *MSH6* mutations).

This paper will cross-compare the precision medical approach to cancer based on pharmacogenomic regimens using companion diagnostics, and the public health approach to precision management of hereditary cancer for 3 cancer types – lung, breast, and colorectal. It will describe methods of early detection and consider how lives can be saved through precise management – from predictive testing and cancer monitoring of the at-risk population, to tailored chemoprevention that fits the needs of the individual. In the population context, a cascade screening “multiplier effect” exists in that relatives can also be assessed and followed for mutations identified in the proband. Cost-benefit analyses (T4 translational research) of medical and public health approaches will be closely examined and compared. Points of commonality between the two approaches will also be discussed, since primary/secondary and tertiary disease prevention represent a continuum. These analyses point to the value of allocating resources towards the health of at-risk populations. Questions remain if particular forms of genetic testing are to become “universalized”, and if the needs of all at-risk groups, including racial-ethnic, are to be addressed.

Keywords: lung cancer, breast cancer, colorectal cancer, Lynch syndrome, genetic testing, cascade screening, universal screening, cost-effectiveness, precision medicine, pharmacogenomics, public health, race, ethnicity

FROM THE HUMAN GENOME PROJECT TO THE PRECISION MEDICINE INITIATIVE

If the twentieth century is known for its success in mapping the human genome, the twenty-first century is becoming equally well known for scientists’ attempts at making genetic interventions “precise” – appropriately chosen, and delivered to the right person and physical target within the human body. The Precision Medicine Initiative (PMI), launched by the Obama administration in January 2015 with a \$215 million outlay in the President’s 2016 Budget and continuing onward in the current administration, brought medicine closer than ever to the ability to tailor medical regimens to the needs of the individual patient [1]. An article by Francis Collins, Director of the U.S. National Institutes of Health (NIH), and Harold Varmus, former Director of the U.S. National Cancer Institute (NCI), which appeared shortly after the announcement, broke the Initiative into two stages: a near-term focus on cancers, and a longer-term aim to yield new knowledge applicable to the broader range of health and disease [2]. Muin Khoury, Director of the Office of Public Health Genomics at the U.S. Centers for Disease Control and Prevention (CDC-OPHG), and Sandro Galea, Dean of Boston University School

of Public Health, followed-up with the affirmation that the PMI could, in time, be used to develop, evaluate, and deliver health interventions with greater “precision” for both individuals and populations [3].

The distance between a strictly individualized approach to precision medicine and one that is population-oriented, fitting the right intervention to the right population, is transcended by a common denominator shared by medicine and public health – cost-effectiveness. Translational research spans several distinct territories, from basic genome-based discovery as it yields candidate health applications (e.g., new genetic tests and therapeutic interventions) - T1 translational research, to evaluation of real-world outcomes (e.g., morbidity and mortality, cost-effectiveness, and quality-of-life indicators) - T4 translational research [4]. In this piece we take the position that whatever the molecular genetic or behavioral approach used, it must make sense dollar-wise such that the interventions are being mustered in an effective and economical way. Our analysis will show that the criterion of cost-effectiveness naturally shifts the prospect of a national precision medicine effort in the population-oriented direction. Though the two may seem like strange bedfellows, both the pharmacogenomics industry and public health community are in agreement that the PMI must be a sustainable effort, so that the real question becomes, “What direction(s) can the PMI effectively take?”

DEFINITIONS OF PRECISION MEDICINE AND PRECISION PUBLIC HEALTH

The definition of a particular medical intervention illustrates both the basic actions to be taken and its scope. Jameson and Longo define “precision medicine” as “treatments targeted to the needs of individual patients on the basis of genetic, biomarker, phenotypic, or psychosocial characteristics that distinguish a given patient from other patients with similar clinical presentations” [5]. Implicit in this definition is the goal of improving clinical outcomes for individual patients, while avoiding unnecessary side-effects that could be incurred by ignoring patients’ individual characteristics. The authors admit that medicine to date has more or less employed such an approach. Hemophilia requires the administration of an appropriate clotting factor, be it factor VIII or factor IX (these days in recombinant form), to stop the bleeding. Clinicians need to undertake a thorough work-up in order to arrive at a precise diagnosis of the hemophilia, which will enable the appropriate therapy to be administered. Choice of antibiotic is another example. For the antibiotic to take hold, the right type of antibiotic must be given for the particular bacterial infection. The latter example suggests that targeted approaches, aimed at particular persons for specific conditions, could actually have population-level applicability, since antibiotics and vaccinations are given on a widespread basis. They are the very opposite of “orphan drugs”, designed to cater to the needs of very rare cases.

Shen and Hwang point out that despite the commonality with past precedent, a substantive shift in methodology between the old medicine and the new medicine is occurring [6]. The practice of medicine has so far remained largely “empirical”. Physicians typically rely on a combination of patient and occasionally family medical history, physical examination, and laboratory data to secure a diagnosis and choose a drug. Treatments are based on a provider’s experience with similar patients. Drugs administered are most often “blockbuster” drugs designed to accommodate the “typical” patient. If the wrong analgesic, antibiotic, or

antiarrhythmic is given, the patient will be weaned off the current drug, and a new one tested until the right drug and dosage are chosen. The idea behind precision medicine is to rely on new biomarkers and genomic tests to “deliver the right treatment to the right patient at the right time” [6]. It is a personally tailored, as opposed to “one size fits all” approach. The fit is “precise” – one person; one drug.

Classic pharmacogenomic examples readily demonstrate this novel approach. Warfarin (brand name Coumadin) dosing allows the frequently used anticoagulant to be titrated to the needs of the patient susceptible to clotting events associated with atrial fibrillation and deep vein thrombosis [7]. Two genes are known to be involved in warfarin therapeutic outcomes – *CYP2C9*, which codes for an enzyme primarily responsible for warfarin metabolism, and *VKORC1*, which codes for the warfarin drug target. Genotyping can yield information useful to guide a person’s initial warfarin dose and allow the clinician to readily stabilize his or her prothrombin measures, a process which usually takes several weeks. Cost-effectiveness studies of genotype-guided dosing have concluded that considerable potential exists for cost savings, but that it cannot be realized until test costs decrease and the uncertainty concerning effectiveness is reduced. The U.S. Centers for Medicare and Medicaid Services (CMS) has consequently adopted a provisional “coverage with evidence development” approach [7]. A physiologic measure, the ratio of the patient’s prothrombin time to a control or “normal” sample, continues to be the professional standard for warfarin dosing. Since the patient is followed with this measure, its use may be considered a tool in “personalized” or individually-tailored medicine.

Imatinib (Gleevec) for chronic myelogenous leukemia (CML) and gastrointestinal stromal tumors is another prime example of the tailoring in drug regimens that may take place. Medical researchers developed this drug over a multi-decade period to inhibit the function of a translocation-related “fusion” gene, *BCR-Abl*, which produces an abnormal tyrosine kinase that is not properly regulated [8]. In initial trials, all of 31 research participants experienced complete remission. The five year survival rate for CML has increased from 31% (1993) to 59% (2003 – 2009) [9]. The drug is administered to patients who are Ph+ (Philadelphia chromosome positive), with effectiveness monitored by white blood cell and platelet counts. Like warfarin, Gleevec targets a particular type of patient and has a very specific chemical target – the ATP-binding site on a particular kinase – and is a drug that can be closely monitored. Gleevec’s cost is about \$3,500 per month, which may evade some patients’ pocketbooks. However, it is covered by Medicare Part D and Medicare Advantage Plans. Both of the above examples describe “personalized medicine” – separating patients into different groups then individually tailoring the treatment to the patient.

Though many authors use the two terms interchangeably, Khoury distinguishes “personalized medicine” from “precision medicine” in that the latter inculcates multiple determinants of health, genetics being one rung, thus can absorb the notion of social determinants as easily as it can molecular determinants. The President’s PMI plan is data intensive in a way that would allow the recording of multiple determinants for large numbers of people, ostensibly through a planned million-person cohort:

Participants will be involved in the design of the Initiative and will have the opportunity to contribute diverse sources of data – including medical records; profiles of the patient’s genes, metabolites (chemical makeup), and microorganisms in and on the body; environmental and lifestyle data; patient generated information; and personal device and sensor data. [1]

Collins and Varmus write that the numerous clinical trials stemming from the PMI and its large-scale cohort will require the building of a “cancer knowledge network” to store all the resulting molecular and medical data in digital form and make it readily deliverable to providers and patients [2]. Simonds and Khoury illustrate this idea with the example of a cancer clinical trials and effectiveness research infrastructure developed by the H. Lee Moffitt Cancer Center. The system is part of its personalized cancer care initiative started in 2006 – Total Cancer Care. The program: (1) integrates data from multiple sources (electronic medical records, biospecimen databases, and molecular data); (2) makes resultant information available to patients by providing active feedback about their health and upcoming appointments and expanded electronic health record; and (3) affords data interfaces for researchers and clinicians [10].

It is to be hoped that the streamlining of cancer clinical trials and centralization of incoming data will reduce costs and increase efficiency over standard medical practices. According to Cancer Research U.K., between 2003 and 2007 cancer trials were accompanied by a 75% increase in administrative costs, a figure in need of remedy [11]. Cost-effectiveness and clinical utility will enter into assessments of the PMI. Public health efforts in the U.S. have to date assumed a twin duty – assessment of the cost-effectiveness of clinical programs, at the same time that a vision of precision medicine’s meaning in terms of population health is being formulated. This vision departs from the medical model of precision health in a number of important respects: (1) it is population-based, with attention to at-risk populations, as opposed to being strictly individualized; (2) the focus is on primary and secondary prevention, rather than frank disease (tertiary prevention); and (3) the emphasis is on interventions that have already demonstrated readiness for large-scale implementation, in contrast to the undertaking of novel clinical trials [12]. To glimpse the future, it is helpful to visit recent experience with precision medicine in the cancer arena. This inspection will take our trek from the individually-focused domain of clinical medicine to the population-oriented territory of public health. The next section will focus on three major cancer categories of mutual interest to clinical medicine and public health – lung, breast, and colorectal cancer – from the medical pharmacogenomics point of view.

PHARMACOGENOMIC INTERVENTIONS AND COST-EFFECTIVENESS

The Precision Medicine Approach to Lung Cancer

Lung cancer is the second most common cancer in both men and women, and is the leading cause of cancer-related death in both genders [13, 14]. Of note, the lung cancer incidence rate for black women is roughly equal to that of white women, despite the fact that they smoke fewer cigarettes [13]. The two major forms of lung cancer are non-small cell lung cancer (NSCLC), and small cell lung cancer (SCLC). NSCLC comprises ~85% of all lung cancers; SCLC ~10-15% [15]. The 5-year survival rate for NSCLC is 21%, suggesting progress that has been and that is yet to be made [16].

Targeted therapies aimed at cancers harboring very specific genetic alterations are becoming more and more common in oncogenomics. A 2012 review of the role of pharmacogenomics in moving genetic association studies from bench to bedside describes the

use of EGFR tyrosine kinase inhibitors (TKI) in the treatment of lung cancer and *HER2* (tyrosine kinase ERBB2)-directed therapies in the treatment of *HER2* (human epidermal growth factor 2)-positive early-stage breast cancer as prime examples of success in the area of cancer pharmacogenomics [17]. A 2016 review of precision medicine approaches in oncology cites ALK (anaplastic lymphoma kinase) fusion oncogene and EGFR (epidermal growth factor receptor (EGFR)) mutations as the main molecular predictive biomarkers supporting NSCLC treatment [15]. Molecular testing for ALK fusion genes has proven valuable. Abbott Molecular already offers a multiplexed assay, the Vysis ALK Break Apart FISH Probe Kit, endorsed by the 2016 National Comprehensive Cancer Network (NCCN) NSCLC practice guidelines [15]. Though ALK fusion gene rearrangements are relatively rare (< 5% of NSCLC cases), clinical responses to targeted inhibitors (e.g., crizotinib) can be quite dramatic [5]. In favor of the precision medicine approach, excluding patients without these mutations can also minimize the exposure of patients to costly and potentially toxic therapies unlikely to benefit them.

EML4-ALK is the specific biomarker used in determining patient efficacy for the choice of a TKI agent such as crizotinib in the tertiary or after-the-cancer-has-arisen management of NSCLC [5]. A 2014 cost-effectiveness study on the use of *EML4-ALK* fusion oncogene testing in first-line crizotinib treatment for patients with advanced NSCLC reveals the complexity inherent in this precision medicine approach [18, 19]. The investigative team found that *EML4-ALK* testing to govern therapeutic decisions improved patient outcomes by an average of 0.011 quality-adjusted life-years (QALYs) while adding extra costs of \$2,725 per patient, of which only \$60 was attributable to the molecular assay itself. The overall interpretation of the cost-benefit calculus changes dramatically, however, when the cost of the companion drug (crizotinib) is considered. The incremental cost-effectiveness ratio is defined as the difference in cost between two alternative interventions, divided by the difference in their effect or impact. The incremental cost effectiveness ratio for administration of the drug itself was \$250,632 per QALY gained. The investigators concluded that the regimen is “likely not considered cost-effective in the current setting” [19]. This assessment was unaltered when the model was subjected to a sensitivity analysis of alternative costs for the molecular testing. States one reviewer, “Where companion diagnostic precision medicine is considered, these assays are by nature tightly coupled to the cost of the specific associated drug” [18].

Assays for EGFR inhibition may be used when other TKI inhibitors, such as gefitinib and osimertinib, are being considered for NSCLC therapy [15]. The U.S. Food and Drug Administration (FDA) has approved two multiplex assay kits, also NCCN endorsed, for this purpose – the *therascreen* EGFR RGQ PCR Kit (for use with gefitinib), and the cobas EGFR Mutation Test (for use with osimertinib). A cost-effectiveness analysis performed by an Australian team compared the use of combined multiplex testing and targeted therapy with NSCLC chemotherapy without testing, and thirdly with best supportive care without testing [20]. The combined strategy resulted in an additional 0.009 life-years (LYs) gained, compared to 1.458 LYs gained in the case of each of the other two strategies. The combined strategy resulted in an incremental cost-effectiveness ratio of \$485,199 (Australian)/QALY comparing combined and best supportive care strategies, and \$489,338 (Australian)/QALY comparing combined and chemotherapy only strategies. Decreasing test and test interpretation costs by half reduced the ratios, but they still remained greater than \$200,000 (Australian)/QALY. The authors concluded that multiplex testing and targeted therapy is not cost-effective as a fourth-line treatment in metastatic lung cancer when first-line treatments such as chemotherapy without pharmacogenomics testing can be employed.

Other predictive biomarkers for NSCLC treatment are on the horizon. For example, *KRAS* mutations can suggest lack of therapeutic efficacy to EGFR targeted therapies. The FDA has cleared *KRAS* mutation detection assays for use in colorectal cancer, but such assays have not yet been approved for use in NSCLC [15].

The Precision Medicine Approach to Breast Cancer

Breast cancer is the most common cancer among American women. It is the second leading cause of cancer death in women, exceeded only by lung cancer [21]. About 85% of breast cancer cases occur in women with no family history of breast cancer. These cases are due to somatic cell mutations which occur as a result of aging, various exposures (such as pre- and postmenopausal hormone therapy), and other life events.

Precision medicine efforts for breast cancer due to somatic mutations fall into at least four categories, two of them – endocrine therapy and *HER2* therapy – being mainstay treatment categories. *HER2*-directed therapies, for which trastuzumab (Herceptin) is often used, are one of the two major pharmacogenomics successes in the cancer area cited by Ritchie [17]. Tamoxifen is a major drug of choice in the category of endocrine therapies, itself being a selective estrogen receptor modulator [15].

Herceptin has proven utility in reducing risk for cancer recurrence after surgery for early-stage *HER2*-positive (*HER2*+) breast cancer, and improving survival in late-stage (metastatic) *HER2*+ breast cancer, but it also poses serious side-effects such as heart damage. Herceptin therapy can also cost a sizable amount, up to \$50,000 per year [22]. Overexpression of the *HER2* gene (*HER2*+ status) is associated with rapid tumor growth and negative diagnostic and prognostic indicators. A systematic review and meta-analysis performed in Canada compared seven different strategies employing immunohistochemistry (IHC) and fluorescence in situ hybridization (FISH) to determine *HER2* status, thus appropriateness of using Herceptin [22]. Each strategy utilized an IHC score (0, 1+, 2+, 3+) alone or coupled with FISH confirmation to form this inference. The incremental cost-effectiveness ratio was lowest when cases with an IHC score of 2+ or 3+ (as opposed to 0 or 1+) were confirmed by FISH, which yielded a ratio of \$3,351 (Canadian) (minimum) to \$12,230 (Canadian) (maximum) per accurately determined case. The cost-effectiveness analysis is favorable given that accurate assessment of *HER2* status is capable of reducing the cost of Herceptin therapy by \$0.6 million per year, and saving \$12 million per year in women who are *HER2*-, thus can be kept off Herceptin [22].

Estrogen-focused therapies have been a part of standard care for more than thirty years, and have displayed an evolution in policy analysts' thoughts about the gold standard for precision management [15]. The Evaluation of Genomic Applications in Practice and Prevention (EGAPP) Working Group was launched by the CDC Office of Public Health Genomics in 2004 to conduct systematic, evidence-based reviews of burgeoning genetic tests and other applications of genetic technologies in transition from research to clinical and public health practice. EGAPP has produced two systematic reviews of the use of gene expression profiling to improve therapeutic outcomes in women with breast cancer. EGAPP's 2009 review examined the validity and utility of three tests – Oncotype DX, MammaPrint, and the H:I (normalized gene expression) ratio [23]. These tests have been designed to go beyond the standard estrogen/progesterone receptor status indicator to predict tumor recurrence risk for women on tamoxifen, for whom alternative therapies might be considered. The EGAPP

Working Group found adequate evidence from the NSABP B-14 randomized controlled trial to support the association between Oncotype DX recurrence scores and 10-year distant metastases in estrogen receptor positive (ER+) patients, and adequate evidence to support the association between RS score and overall chemotherapy benefit, particularly for patients in the high risk category [23]. Recent publication of interim results for the TAILORx study has shown a further association between recurrence score and 5-year disease-free survival and distant recurrence in patients at low risk [24].

A follow-up systematic review by the EGAPP Working Group published in 2016 confirmed its previous findings but also noted the lack of direct evidence that the use of Oncotype DX improves clinical outcomes [25]. It also highlighted contradictory cost-effectiveness results in studies performed in the U.S. (for which \$2,000 in cost savings per patient were due to a decrease in post-testing chemotherapy use) and the U.K. (for which an incremental cost-effectiveness ratio of 26,940 £/QALY gained were due to an increase in chemotherapy use) [25]. The U.K. National Institute for Health and Care Excellence (NICE) Diagnostics Advisory Committee concluded that, under the assumption of equal chemotherapy benefit for all Oncotype DX risk categories, the test is not cost-effective at its current pricing level. In the first EGAPP review, data were adequate to support an association between the MammaPrint Index and 5- to 10-year metastasis rates, but the efficacy relative to classical clinical factors was unclear. More conclusive results await the completion of the MINDACT trial. For the H:I ratio test, populations studied were quite heterogeneous, and the test's commercial offering was based on a single study in women with primary, untreated breast cancer.

The Precision Medicine Approach to Colorectal Cancer

Colorectal cancer (CRC) is the third most common cancer in both men and women in the U.S. [26]. It is the third leading cause of cancer deaths when men and women are considered separately, and the second leading cause in both sexes combined.

Considerable effort has been placed into targeted therapies and companion diagnostics for CRC. About 70-80% of patients present with resectable localized disease, treated by surgery and often followed by adjuvant therapy [27]. CRC patients with advanced disease may receive first-line chemotherapy, or chemotherapy and radiation before surgery is considered. The EGAPP Working Group published in 2009 a systematic review of one first-line chemotherapeutic agent, irinotecan, which may be accompanied by *UGT1A1* genotyping to check for ability to adequately clear the drug [27]. Such genotyping aids decisions to either increase drug dose for more aggressive therapy, or switch to common alternate drugs, bevacizumab or cetuximab, for instance, in individuals with reduced clearance at risk for adverse events. EGAPP had two major findings: (1) unless patients receive a certain threshold dose of irinotecan, the increase in risk for toxicity is not significant, thus testing may not be warranted; and (2) reducing the dose of irinotecan (personalized dosing) to avoid adverse events may lead to more cases of unresponsive tumors than instances of adverse events avoided. It is inconclusive that benefits outweigh harms in the application of a precision approach here.

The alternate drugs mentioned above are positioned among the three main classes of targeted therapies approved for metastatic CRC: (1) multikinase inhibitors; (2) angiogenic inhibitors; and (3) anti-EGFR antibodies [15]. Up to 50% of CRC patients respond to anti-

EGFR therapy, which includes cetuximab [28]. *KRAS* wild-type status is considered an important factor in achieving a clinical response from this category of therapy [29]. However, 40-60% of patients with wild-type status do not respond to such therapy. Data suggest that *BRAF* gene status also plays a role in anti-EGFR response, and that the *BRAF* V600E mutation, present in 5-10% of CRC tumors, can lead to a positive response. To date the FDA has cleared two genetic testing kits, the *therascreen* *KRAS* kit from Qiagen, and the cobas *KRAS* Mutation Test from Roche [15]. The American Society for Clinical Oncology (ASCO) and three other professional organizations released new consensus guidelines in 2015 strongly recommending *KRAS* mutational testing for patients being considered for anti-EGFR therapy, and that *BRAF* V600 testing also be considered.

Table 1. Pharmacogenomic/Companion diagnostic approach – 3 cancers

Condition	Therapy	Biomarkers	Cost-Effectiveness	References
Non-small cell lung cancer (NSCLC)	Tyrosine kinase inhibitors	<i>EML4-ALK</i>	\$255,970/QALY gained	Djalalov et al. [19]
		EGFR	\$489,338 (Austr.)/QALY gained	Doble et al. [20]
HER2+ Breast cancer	Herceptin	IHC, FISH	\$3,351 – 12,230 (Can.) saved per case	Dendukuri et al. [22]
ER+ Breast cancer	Endocrine	21-gene assay	26,940 £ (Brit.) cost/QALY gained	EGAPP [25]; Ward et al. [33]
Metastatic colorectal cancer	Topoisomerase 1 inhibitor (TOP1) – irinotecan	<i>UGT1A1</i> genotyping	ambivalent results – reducing toxicity vs. reducing tumor burden	EGAPP [27]
	Anti-EGFR	<i>KRAS</i>	\$7,500 – 12,400 saved per case	EGAPP [30]; Vijayaraghavan et al. [31]
			\$180,000/QALY gained	EGAPP [30]; Shiroiwa et al. [32]

The EGAPP Working Group conducted a systematic review of companion diagnostic use of *KRAS* and *BRAF* mutation testing in anti-EGFR therapy in 2013 [30]. The systematic review looked at multiple pooled assessments, each consisting of up to seven studies, which together indicated statistically significant increased response rates to cetuximab and other anti-EGFR drugs, reduced risk of disease progression, and enhanced overall survival with *KRAS* wild-type status. EGAPP cited a cost-effectiveness study of *KRAS* testing in metastatic CRC patients in the U.S. and Germany [30, 31]. For the U.S. patients, use of *KRAS* testing to select patients for EGFR inhibitor therapy saved \$7,500 to \$12,400 per case. A second cited study from Japan displayed an incremental cost-effectiveness ratio for cetuximab with *KRAS* testing to be \$180,000 per QALY gained compared to therapy without testing [32]. Due to this cost, the investigators concluded that the protocol was not cost-effective, even when treatment was limited to patients with wild-type *KRAS*. Two of three studies looking at *BRAF* testing found associations similar to the *KRAS* studies in terms of progression-free and overall survival, but these findings, however, were not contingent on whether or not cetuximab was included in the combination therapy. Thus, while the review supported recommendations for a precision

approach using *KRAS* mutation testing, it found insufficient evidence to link *BRAF* V600E mutation testing with treatment response independent of prognostic association.

Table 1 summarizes the cost-effectiveness and descriptive findings for the pharmacogenomics or companion diagnostic precision medicine approach to the three cancers.

TAKING PRECISION MEDICINE BEYOND THE PERSONALIZED LEVEL

One argument against the informativeness of the above studies is that they represent a personalized medicine approach, but not a precision medicine approach in its full capacity [3]. The electronic storage of information, which can be multifactorial, including relevant lifestyle, would seem to be crucial to maximizing benefits and minimizing cost. The investigative team looking at the infrastructure characteristics of the Lee Moffit Cancer Center “Total Cancer Care” program also examined six other major healthcare programs engaged in cancer care comparative effectiveness research in genomic and precision medicine [10]. Four of the researched programs – at Duke University, Kaiser Permanente, University of Pennsylvania, and the Fred Hutchinson Cancer Center – had established a complex infrastructure (with data and biospecimen registries and multidisciplinary research teams), were engaged in “knowledge generation” (via randomized controlled trials and observational studies), and had reached the stage of “knowledge synthesis” (horizon scanning, evidence synthesis, and decision modeling). These programs display a depth of information and range of multidisciplinary expertise that is reflective of the type of knowledge synthesis of which the PMI’s million person cohort will be capable.

The Duke University and Kaiser Permanente teams noted a number of strategic challenges to the amassing of cancer study data – limited data quality, large variation in genomic methodology used, and poor demonstration of clinical utility for the genomic tests supplying the data [10]. These observations point out challenges that could foreseeably face PMI investigators attempting to collate information from the expansive precision medicine cohort. The Kaiser Permanente group was able to show that in screening for Lynch syndrome, a hereditary form of CRC, microsatellite instability testing (MSI) was preferable compared to immunohistochemical staining (IHC). In the treatment phase, the investigators found that screening for *KRAS* and *BRAF* mutations improved the cost-effectiveness of anti-EGFR therapy, but that the cost of the therapy surpassed generally accepted cost-effectiveness thresholds of \$100,000/quality-adjusted life-year. These findings allude to the capability of the PMI to develop new data on useful oncogenomic screening, mutational testing, and therapeutic procedures, and to the correspondingly likely possibility that many of the discoveries, while being individually beneficial, could elude effectiveness for the clinical population as a whole.

The PMI will no doubt be carried in new directions that have not yet been quantified, however. NCI is engaged a new type of clinical trial called “NCI-MATCH” [34]. In this innovative program, adult cancer patients are assigned to targeted treatments based on the genetic abnormalities in their tumors, regardless of the type of cancer they have. This concept represents the therapeutic end of what has been happening with diagnostics. *KRAS* and EGFR mutation testing is now occurring for multiple cancer types. Why should cancer therapies be restricted to just one cancer type? New management models may also evolve. The data

infrastructure supporting precision medicine can and is being used to develop procedural algorithms that combine genetic testing with genetically targeted therapies. These algorithms, if tailored to the lay person, can then be used by both medical providers and patients in collaboration, improving the effectiveness of the prescribed regimen. Shen and Hwang use *CYP2C9* (they cite *CYP450*) testing for warfarin dose performed at home first by nurses then by patients as an example [6]. This linkage of “big” or “rich” data and the development of new, useful algorithms is cited by multiple authors [2, 5, 35]. The issue is whether providers of various types, and consumers, can understand the test results and appreciate the connection to one-size-does-not-fit-all therapeutic management [36].

Authors discussing the translation of big data into usable guidelines and algorithms are not just limiting the payoff to individualized treatment, however. Jameson and Longo, for instance, speak of not just a pharmacogenomic future, but one in which “guideline-based screening”, e.g., colonoscopy, can be targeted on the basis of age and family history [5]. Family health history is one of several tools, including individualized genetic testing and family cascade testing, fueling the public health drive towards precision interventions [37, 38].

The public health approach to precision medicine, or “precision public health”, is highly evidence-based. Precision public health is exemplified in the Centers for Disease Control and Prevention’s emphasis on the implementation of Tier 1 genetic tests that have passed systematic review for analytic and clinical validity and utility – family history-based hereditary breast and ovarian cancer (HBOC) genetic testing (*BRCA1/2* mutations in relatives), and hereditary nonpolyposis colorectal cancer genetic testing (Lynch syndrome *MLH1*, *MSH2*, *MSH6*, *PMS2*, *EPCAM* mutations) [39]. Indeed, genetic counseling and testing for HBOC are already incorporated into healthcare reform as services not requiring co-pay for individuals deemed at risk by their providers [40]. The PMI promises much more, however, and part of the vision of public health is that precision techniques can be used to direct genetic preventive strategies to those subsets of the population that will derive maximal benefit [41].

PUBLIC HEALTH INTERVENTIONS AND COST-EFFECTIVENESS

The Precision Public Health Approach to Lung Cancer

It has been remarked that “although personalized treatments can help save the lives of sick people, prevention applies to all” [3]. This comment applies especially to lung cancer, which can be tackled as we have seen individually and after it has manifested, or by using a preventive, population-based approach. Initial genome-wide association studies (GWAS) published by several investigative teams in 2008 were suggestive of lung cancer susceptibility genes being situated on the long arm of chromosome 15 [42]. The studies were all large (3,500 to 14,000 participants) and replicated, yielding strong evidence for an association between SNP variations at 15q24/15q25.1 and lung cancer. Thorgeirsson et al. found a highly significant association ($P = 1.5 \times 10^{-8}$) between a common variant in the nicotinic acetylcholine receptor gene cluster on chromosome 15q24 and smoking frequency, with an odds ratio of 1.31 (1.19 – 1.44, 95% C.I.) between nicotine dependent cases and low quantity smokers plus population controls [43]. Studies by Hung et al. [44] and Amos et al. [45] found odds ratios between 1.21 and 1.77 for associations between the nicotinic acetylcholine receptor regions 15q25 and 15q25.1 and lung

cancer in ever smokers, the former accounting for 14% (attributable risk) of the lung cancer cases in the first study. The second study examined 2,724 NSCLC cases, the same type of cancer being treated in later stages by pharmacogenomics regimens.

More recent GWAS in never-smoking Asian females have pointed out genetic associations independent of smoking status. Case-control studies of never-smoking Asian females funded through the National Institutes of Health [46] and the Mayo Foundation [47] have identified genetic variants in the 3q28 and 13q31.3 regions associated with risk for lung cancer (N = 754 to 7,254 participants). These associations show both statistical significance ($P = 10^{-6}$ to 10^{-8}) in terms of odds ratios and allelic risk, and biological plausibility (association with the regulation of cell proliferation and division). These two lines of discovery – lung cancer in connection with nicotine dependence and independent of it – could beneficially lead to both personalized smoking-cessation interventions, and to increased screening of people at risk for lung cancer [41]. The difficulty is that the association studies are at the primary research (T1) stage and do not yet imply clinical validity.

Precision medicine in public health terms involves targeting groups at risk. Various professional societies have developed guidelines for lung cancer screening, generally beginning at age 55 [48]. The NCCN lung cancer screening guidelines recommend screening individuals age 50-55 years, those who have between 20 and 30 pack-years of exposure, and who exhibit one additional risk factor, such as family history. The relative risk of developing lung cancer is 1.8 if the individual has at least one first-degree relative with lung cancer, and 3.0 given two first-degree relatives with the condition [49]. The positive and negative predictive values for lung cancer appearing in a proband's first-degree relatives are 89.9% and 99.1%, respectively [50]. In the Utah Family High Risk Program, the cost of taking a family health history varied between \$10 and \$25 depending upon receipt of follow-up educational interventions [51]. These figures indicate cost-effectiveness for the use of family history in risk assessment for lung cancer.

Public health programs are especially concerned with the rights and welfare of underserved groups, an aim that is built into public health codes of ethics [52]. Surprisingly, of the 58,160 lung disease studies published between 1993 and 2013, less than 5% reported the inclusion of minority participants [53]. NIH is presently consulting researchers adept at recruiting under-represented groups into studies as part of PMI Research Cohort formation. An admixture study of 1812 African Americans performed by the Karmanos Cancer Institute in Detroit, MI demonstrates what can come out of the use of the PMI Cohort. Excess African ancestry was observed on chromosome 3q among ever smokers with NSCLC, a chromosomal region identified by previous studies with mostly persons of European ancestry [54].

The Precision Public Health Approach to Breast Cancer

About 10 to 15% of women diagnosed with breast cancer have germline mutations in the *BRCA1* or 2 genes. Between 10 and 30% of women under age 60 diagnosed with triple-negative breast cancer (cancer which does not have receptors for estrogen, progesterone, or *HER2/neu*) display a *BRCA1/2* mutation [55]. Ashkenazi Jewish ancestry confers an increased risk, though such mutations are by no means relegated to just one group. Like lung cancer, the public health approach to hereditary breast and ovarian cancer (HBOC) focuses on primary prevention before disease has appeared. Primary prevention can be conducted through a variety of means, several

of which fit under a public health precision model. A study out of the Cleveland Clinic Genomic Medicine Institute compared two methods for cancer risk assessment – “family history-based risk assessment” and “DTC [Direct-to-Consumer] personal genomic screening,” the latter using a variety of risk alleles [56]. Of 22 high risk females appearing in clinic, family history classified eight individuals as being at risk for breast cancer, but only one of the eight was classified as high-risk through personal genomic screening method.

Family history is a quick way of identifying risk, and has value in this instance as it does with lung cancer. Valdez et al. note that the relative risk of developing breast cancer is 1.8 and ovarian cancer 2.9 if the individual has at least one first-degree relative with these conditions [49]. It is 3.0 and 14.7 given two affected first-degree relatives. The positive and negative predictive values for these cancers appearing in a proband’s first-degree relatives are 89.1% and 98.9% for breast cancer, and 76.1% and 99.3% for ovarian cancer [50]. The U.S. Preventive Services Task Force (USPSTF) has conducted evidence reviews of genetic testing for the key mutations involved in HBOC, *BRCA1* and 2. It recommends:

Primary care providers screen women who have family members with breast, ovarian, tubal, or peritoneal cancer with 1 of several screening tools designed to identify a family history that may be associated with an increased risk for potentially harmful mutations in breast cancer susceptibility genes (*BRCA1* or *BRCA2*). Women with positive screening results should receive genetic counseling and, if indicated after counseling, *BRCA* testing. [57]

The CDC-OPHG classifies the use of family history of known breast/ovarian cancer with deleterious *BRCA* mutations as Tier 1 [39]. CDC defines Tier 1 genetic interventions as those supported by clinical practice guidelines based on thorough systematic review. These modalities are ready for implementation not just on the individual but on the level of the at-risk population as well [38].

Family history, however, is part of a train of diagnostic interventions, including genetic counseling and genetic testing. The latter can lead to annual screening via MRI or to surgery. A 2012 cost-effectiveness analysis of *BRCA1/2* testing of women ≥ 35 years at elevated risk of carrying a mutation, considering the eventual use of these MRI and surgery, determined genetic testing to be cost-effective if testing cost were $\leq \$8,948$ [58]. Currently targeted *BRCA1/2* mutation testing ranges from \$4,500 to \$650 [58, 59].

Economies of scale operate when identifying persons at risk for cancer. Identifying single individuals can be expected to be less efficient than pinpointing families at risk, just as using information reflecting population risk data can be expected to be more efficient than utilizing separate family histories. Cascade screening is the testing of successive test positive family members starting with a positive index case. Two studies delineate that the success of *BRCA1/2* cascade screening in affected families, as measured by actual uptake of genetic testing, is a function of ability of family members to communicate with one another, and to attend a clinical session [60, 61]. Uptake rates of 54% (Utah study) and 73% (Manchester portion of U.K. study) were achieved when these conditions were satisfied. The London portion of the U.K. study, which covered a more dispersed population, achieved 62% for those clinically seen. George et al. indicate that the cost of *BRCA* testing in 30 at-risk relatives can be brought down from a minimum of \$66,000 to \$12,000 once the responsible mutation has been identified in a family member [62].

On a population level, it is possible to gather information on early-stage breast and ovarian cancer, and to report aggregate information back to participating institutions. A breast cancer incidence study utilizing the Connecticut Tumor Registry found that the ability to detect cases depends on the relative population size of the groups being assessed (here white versus nonwhite) [63]. Population-based risk assessment has the advantage of detecting *BRCA1/2* carriers with a negative family history. Clinical validity goes up with the prevalence of a disorder in a given population. Rubinstein et al. performed a decision analysis of *BRCA1/2* testing in American Ashkenazi Jewish women aged 35-55 years [64]. At a cost of \$460 for founder mutation testing, the investigators concluded that such a program is cost-effective, amounting to \$8,300/QALY gained.

The PMI, like state cancer registries, is especially geared towards targeting at-risk individuals and populations. The CDC notes that state health departments have engaged in bidirectional reporting, i.e., identification of cases from the state tumor registry, and reporting back of information to participating facilities. The Michigan Department of Health and Human Services and Connecticut Department of Health have both identified thousands of cases of breast and ovarian cancer suggesting risk for HBOC, and returned back facility-specific data [65]. In the case of Connecticut, facility-specific reports on numbers of breast and ovarian cancers, compiled from 3,792 cases in the state cancer registry, were reported back to providers to alert them that patients might be at an increased risk for HBOC. Staff at 70% of the 32 involved hospitals also requested and received an HBOC training session.

In the age of electronic health records (EHRs), systems can be designed to provide physicians with decision support tools that alert them to the need for genetic testing, and assist with interpretation of results and potential impact on patients and their families [11]. It is also possible with EHR systems to flag patients who are members of high-risk families to make them aware of their risk status and available options [66, 67].

The Precision Public Health Approach to Colorectal Cancer

The hereditary form of CRC that has received the most public health and medical attention is hereditary nonpolyposis colorectal cancer (HNPCC) or Lynch syndrome (LS), which produces only a small number of polyps or none at all. LS is the most common heritable cause of CRC, representing 1 in 35 cases [66]. Whereas the lifetime risk for developing CRC is 2 to 5% in the general population, it is 80% in those with LS.

Family history as an instrument for performing cancer risk assessment in first- and second-degree relatives is even more accurate for CRC than for the other two families of cancers. Valdez et al. report that the relative risk for CRC is 2.2 given a first-degree relative with the condition, and 4.0 given at least two first-degree relatives with CRC [49]. Lynch syndrome is notoriously underdiagnosed, however. The vast majority of families with a history of CRC do not know they may have LS, or even that a genetic test is available [66]. Nevertheless, the EGAPP Working Group, using a chain of evidence methodology comparing four preliminary testing (MSI, IHC, and *BRAF*) and mismatch repair (MMR) gene strategies leading to medical and surgical management, found that adequate evidence exists that an appropriate testing strategy can improve clinical outcomes for patients and their families [68].

A precision public health approach to Lynch syndrome entails spotting cases before the management is made more complex by disease advancement, coupled with identifying at-risk

relatives free of disease. A 2014 consensus statement by the U.S. Multi-Society Task Force on Colorectal Cancer looked at initial approaches for index case identification. Use of clinical criteria (e.g., the Revised Bethesda Guidelines) and a CRC risk assessment tool using family history – “selective approaches” used to identify a range of patients – both showed adequate sensitivity in identifying individuals with germline mutations, but up to 28% of LS patients can be missed with a liberal interpretation of the revised guidelines [69]. A more “universal approach” assessing LS risk based on IHC testing of all incoming cases of CRC was found to have greater sensitivity than selective strategies including the use of the Bethesda guidelines. Such an approach is still shy of being considered population-wide risk assessment in that testing begins with confirmed colorectal cancer cases. Multiple studies have shown that: (1) the systematic application of testing among patients with newly diagnosed CRC could provide substantial clinical benefits at acceptable costs; and (2) adopting a “universal” approach towards CRC genetic testing is cost-effective [69]. Palomaki et al., for example, found that a strategy employing IHC and *BRAF* preliminary testing followed by MMR mutation testing in *BRAF* negative cases would cost an average of \$18,863 per LS case detected [70].

Having identified an index case, the public health approach is then to move on to relatives to identify those at risk for LS, and those who are not. The EGAPP Working Group cites seven studies showing how uptake of colonoscopy by relatives with LS ranged from 53 to 100% [68]. Sharaf et al., in a sub-analysis of four select articles from a broader LS studies review, concluded that 52% or less of the first-degree relatives received LS genetic testing [71]. This number was critiqued by Jasperson, who noted that the Sharaf analysis excluded a large study containing 466 family members composed almost exclusively of first-degree relatives at high-risk of developing LS [72]. The latter study found 75% of the members to have been tested for LS mutations.

The cost of cascade testing is also a consideration. The per mutation cost of MMR gene testing for LS can decrease from \$1,000 to \$350 once a specific familial mutation has been identified in the proband [59]. The consequence is that the cost per LS index case can decrease from \$18,863 to \$13,000 [68]. In the most comprehensive cost-effectiveness assessment of universal and “near-universal” genetic screening to date, covering seven LS studies that also looked at medical/surgical follow-up and testing of relatives, Grosse found that all except one reported incremental cost-effectiveness ratios less than the threshold \$100,000 per life-year or quality-adjusted life-year gained [73].

As with HBOC, collection and reporting of LS data has occurred at the state level. Michigan identified 10,000 CRC cases from its cancer registry, and returned facility-specific data and educational materials to 145 reporting institutions [74]. Connecticut reported back information on 3,517 CRC cases in its cancer registry to targeted practitioners at acute care hospitals. These bidirectional reporting efforts show that health-related information may be stored *en masse* for both practical and research purposes (as in the PMI Cohort), and can be reissued for clinical and public health purposes.

The Colorado Department of Public Health and Environment also targeted educational outreach relating to hereditary CRC to 430 medical providers and 200 at-risk cases [74]. A survey was conducted which showed that 98% of provider and patient respondents thought that the information was clear and useful, many patients having indicated they engaged in further dialogue with their physician, a genetic counselor, or a family member. About 1/3 of the patient respondents communicated that they planned to have a risk assessment as a result of receiving the materials. The Colorado educational efforts were conducted by mail. An extensive, 33-

study article review by Naylor et al. found that further patient education involving phone or in-person contact combined with patient navigation of resources can lead to improvements on the order of 15% in colorectal screening rates in minority populations [75].

Table 2 outlines the array of precision public health efforts, which involves targeting of screening, genetic testing, and education for the three cancer conditions.

Table 2. Public health precision approach – 3 cancers

Condition	Genetic test	Cost-effectiveness	References
Familial lung cancer	Family history (FH)	*FP rate: 1.9 (female) – 6.1 (male) FN rate: 29.1 (female) – 37.5 (male) **PPV: 81.0 (68.6 – 90.1)*** NPV: 97.1 (96.0 – 98.0) Cost \$10 – 25/FH taken	Ziogas and Anton-Culver [50] Johnson et al. [51]
Hereditary breast and ovarian cancer (HBOC)	<i>BRCA1/2</i>	Cost-effectiveness threshold \$8,948 (current testing \$650 – 4,500) \$8,300/QALY gained (U.S. Ashkenazi population)	Goodman [58] Rubinstein et al. [64]
Hereditary nonpolyposis colorectal cancer (Lynch syndrome – LS)	Multi-gene testing (<i>MLH1</i> , <i>MSH2</i> , <i>MSH6</i> , <i>PMS2</i> , <i>EPCAM</i>)	\$18,863 cost/index case \$13,000 cost/relative \$29,600 – 63,900/QALY gained (“universal” testing)	EGAPP [68]; Palomaki et al. [70] Grosse [73]

* False positive (FP) and false negative (FN) rates.

** Positive predictive value (PPV) and negative predictive value (NPV).

*** 95% Confidence interval.

CONCLUSION: CONTINUITY AND EMERGENCE IN PRECISION HEALTH APPROACHES

A major point brought out by the two tables is that pharmacogenomic regimens cost considerably more than primary prevention approaches to cancer management. From the articles reviewed herein, the former often exceed cost-effectiveness thresholds, though this conclusion need not necessarily be true for the regimens that are being offered. The cancer drug being prescribed is typically the main contributor to the cost, as opposed to the companion diagnostic, which can actually bring the price down. One can then view this conclusion in three ways: (1) optimistically, economies of scale or institutional policy changes might ultimately bring the cost of the pharmacogenomic regimen down; (2) the value of a person’s life is to be held paramount, thus the costs incurred, from a private perspective, are worth it; or (3) the value of the primary prevention approach, due to its cost-effectiveness, is to be emphasized.

The medical and public health approaches are not to be viewed as mutually exclusive. Their territories are more like the circles of a Venn diagram which intersect with plenty of shared space in the middle. Both the CDC and its EGAPP program have devoted considerable attention to companion diagnostics and the attempt to prove that they have overall utility, including cost-effectiveness. Public health has an evaluative role that dips into hospital-based interventions. The national view is more one of mergence [3]. The fact that *BRCA1/2* genetic testing takes off where chemotherapeutic approaches to breast cancer leave off, in terms of the host cancer's hormone receptor status, indicates that the domains of the primary/secondary and tertiary prevention camps are complementary. It would be idealistic to assume that predictive genetic testing plus monitoring could eliminate all tumors before they spread. Both ends of the prevention continuum are needed, and the more targeted they are, the better. It is also important to recognize that the medical and public health approaches both defy stereotyping. The use of *KRAS* testing in anti-EGFR therapy of metastatic colorectal cancer can be cost-saving. The value of a public health approach genetic to lung cancer is limited by the current state of GWAS findings and the heavy influence of gene-environment interactions in the genesis of lung cancer. Indeed, some would argue that federal and state policy approaches towards smoking and lung cancer should take center stage.

Policymakers have a role in deciding allocation of healthcare dollars. In providing arguments for and against utility in this paper, we are not advocating a withdrawal of dollars from either medical or public health oncogenomic approaches. The case has been made for a more detailed consideration of the proportion of dollars that go towards prevention, however. The paper has not dealt just with chemotherapy, or just with Tier 1 genetic testing, however – emphasis has been placed on a precision approach for both. In public health, this nuance translates into tailoring the intervention towards communities at-risk or in-need. It will be more cost-effective thereby, and will achieve the ethical standard of addressing the health of all by attending to those most in need.

A final point should be made about the medical and public health precision approaches that are emerging. The medical approach is showing healthy signs of growth. The PMI Research Cohort will grant it the ability to host more clinical trials with suitable cohorts of participants, and to speed up the process of conducting clinical trials. As NCI plans, some of these trials will cross typological borders and target treatments based on somatic abnormalities in the tumors regardless of cancer type [34]. Public health research will also benefit from the PMI Cohort, especially in instances where major germline mutations have not turned up and GWAS are actively identifying lower risk alleles having a cumulative effect. Given the thought being given to participating groups, the discovery of new risk alleles will most certainly benefit diverse communities. The promise of tapping into lifestyle and environmental factors as data on the cohort participants builds will strengthen prevention approaches even further. The word “precision” also applies to the educational component of health programs. Educational efforts can become more tailored to the needs of at-risk groups as the data accumulates. Precision public health does not end with the target molecule, but with the whole person and the community to which he or she belongs.

Chapter 70

NEUROPSYCHOLOGICAL PROFILE OF PEOPLE WITH WILLIAMS SYNDROME (WS)

Anne-Sophie Pezzino, Nathalie Marec-Breton and Agnès Lacroix*

Center for the Psychology of Cognition, Communication and Behavior
University of Rennes 2, Rennes, France

ABSTRACT

Williams syndrome (WS) is a genetic neurodevelopmental disorder (prevalence close to 1 in 20,000-30,000 births) resulting from the deletion of 16-25 genes on the long arm of Chromosome 7 (Scherer & Osborne, 2006). Individuals with WS have an intelligence quotient of 40-70 (Howlin, Davies, & Udwin, 1998). They have a unique neuropsychological profile, characterized by an apparent dissociation between cognition and language, as language is relatively well preserved, compared with other cognitive skills (Karmiloff-Smith, et al., 2004; Martens, Wilson, & Reutens, 2008). However, a more complex profile is now emerging, with good lexical, short-term memory (especially auditory-verbal) and face processing skills, but visuospatial (especially local processing of information), executive (planning and inhibition), memory (working memory and long-term) and attentional deficits (Bellugi, Lichtenberger, Jones, Lai, & George, 2000; Schmitt, Eliez, Warsofsky, Bellugi, & Reiss, 2001; Fayasse & Thibaut, 2003; Menghini, Addona, Costanzo, & Vicari, 2010; Costanzo et al., 2013; Dessalegn, Landau & Rapp, 2013).

Individuals with WS also have specific auditory-perceptual cognitive skills (hyperacusis), category-specific perception of speech sounds (Majerus, Palmisano, Van Der Linden, Barisnikov, & Poncelet, 2001; Majerus, Barisnikov, Vuillemin, Poncelet, & Linden, 2003), and musical skills that exceed their cognitive level (Levitin, Cole, Lincoln, & Bellugi, 2005). Other behavioral characteristics include hypersociability (Jones et al., 2000; Mervis, Morris, Klein-Tasman, et al., 2003).

In this chapter, we provide a review of the literature on the specific neuropsychological profile of individuals with WS, from a cognitive-behavioral and neuroanatomical point of view. Early studies of the neuropsychological profile in WS focused on the dissociation between cognition and language. Since then, research has shown this syndrome to be more complex.

* Corresponding Author's Email: agnes.lacroix@univ-rennes2.fr.

Our aim is to highlight the heterogeneity of the cognitive profiles observed in this syndrome, and to identify the factors that might explain this heterogeneity. The complexity and specific features of the neuropsychological profile in WS need to be understood in order to develop therapeutic and learning methods adapted to the developmental pace of individuals with WS.

Keywords: genetic syndrome, Williams syndrome, neuropsychological profile, learning abilities

INTRODUCTION

Williams syndrome (WS) is a rare genetic disease (one case per 20,000 births) caused by a microdeletion on the long arm of Chromosome 7 (7q11.23) leading to the loss of 16-25 genes (Scherer & Osborne, 2006). At the cognitive level, individuals with WS have an intelligence quotient (IQ) of about 40-70 (Howlin et al., 1998; Mervis, Morris, Bertrand, & Robinson, 1999). Their unique neuropsychological profile is characterized by a dissociation between oral language (relatively preserved) and other (impaired) cognitive abilities (Hoffman, Landau, & Pagani, 2003; Tager-Flusberg, Plesa-Skwerer, Faja, & Joseph, 2003; Karmiloff-Smith et al., 2004; Reiss, Hoffman, & Landau, 2005; Meyer-Lindenberg, Mervis, & Berman, 2006; Martens et al., 2008; O'Hearn, Courtney, Street, & Landau, 2009). Neuroanatomical studies suggest that these cognitive profiles can be explained by brain defects: preservation of the frontotemporal lobe (oral language), but parietal lobe (visuospatial skills) deficiency (Bellugi et al., 2000; Martens et al., 2008; Eisenberg, Jabbi, & Berman, 2010; Thomas, Purser, & Van Herwegen, 2012).

In this chapter, we explore the complex neuropsychological profile of individuals with WS, which goes far beyond a straightforward dissociation between language and other cognitive skills. Research on the neuropsychological profile of individuals with WS has been based on four major domains: intellectual ability, perception (auditory and visual), language and, more recently, memory and executive functions. Results suggest specificity and considerable variability in cognitive abilities (Bellugi et al., 2000; Martens et al., 2008). The purpose of this chapter is to analyze more recent studies, in order to find explanations for the heterogeneity of the neuropsychological profile in WS. From a developmental perspective, we attempt to understand the complexity and characteristics of this profile.

INTELLECTUAL ABILITY

Historically, studies have relied on the IQ of individuals with WS to characterize their cognitive profile (Howlin et al., 1998; Mervis et al., 1999; Martens et al., 2008). Research has highlighted a syndrome-specific dissociation between language skills and other cognitive abilities (Mervis & Klein-Tasman, 2000; Martens et al., 2008). Studies show that verbal IQ is higher than performance IQ among individuals with WS (Boddaert et al., 2006; Searcy et al., 2004). It should be noted that there is less heterogeneity in subtests measuring performance IQ (Searcy et al., 2004).

Studies have yielded discrepant findings on the IQ of children with WS across development. Some studies have demonstrated a decline in IQ (Gosh & Pankau, 1994), while others have found an increase of 3-17 points (Udwin, Davies, & Hosylin, 1996).

There therefore seems to be considerable variability in results on intellectual ability and, consequently, in behavioral abilities. For example, studies have shown that teenagers with WS have difficulty with Piagetian tests of number, weight and substances that children are normally able to perform successfully by the age of 8 years (Dehaene, 1997). However, while some adults with WS have difficulty with arithmetic, others are able to master basic operations such as addition, subtraction and division (Howlin et al., 1998).

More recently, research has suggested that intellectual level is relatively stable (Searcy et al., 2004), with most studies ruling out a link between intellectual ability and the development of cognitive processes underlying the learning behavior of individuals with WS (Majerus et al., 2003; Menghini, Verucci, & Vicari, 2004; Steele, Scerif, Cornish, & Karmiloff-Smith, 2013). It is now acknowledged that full-scale IQ alone does not reflect the variability in cognitive skills and behaviors of people with WS. For example, although a longitudinal study by Udwin, Davies, and Howlin (1996) of 23 participants with WS (IQ = 70) revealed weaknesses that could be correlated with IQ (WAIS-R; 1981) in reading, spelling and arithmetic tasks, other results suggest a lack of connection between intellectual ability and the acquisition of reading skills (Majerus et al., 2003; Menghini et al., 2004; Steele et al., 2013).

To sum up, previous findings highlight the importance of describing the cognitive skills elicited by the tasks administered to individuals with WS. In the rest of this section, we therefore describe the cognitive skills of individuals with WS, including visual and auditory perception, oral language, memory, and executive functions.

PERCEPTUAL SKILLS (VISUAL AND AUDITORY)

One way of exploring the marked heterogeneity of individuals with WS is to study their perceptual abilities, both auditory (categorical and allophonic perception) and visual (visuospatial and face processing).

Auditory processing performances seem atypical in WS (Majerus et al., 2003). The hyperacusis that is frequently mentioned in studies of WS may induce categorical and allophonic perception of speech sounds, preventing the formation of stable phonological representations (Majerus et al., 2003; Nazzi, Paterson, & Karmiloff-Smith, 2003; Eckert et al., 2006; Bogliotti, Serniclaes, Messaoud-Galusi & Sprenger-Charolles, 2008; Martens et al., 2008; Majerus D'Argembeau, Martinez Perez et al., 2010).

These auditory peculiarities could explain other cognitive and behavioral specificities (Carrasco, Castillo, Aravena, Rothhammer, & Aboitiz, 2005; Levitin et al., 2005). Surprisingly, despite their lower pain threshold and fearful reactions to specific sounds, some people with WS spontaneously exhibit a strong interest in music (Carrasco et al., 2005; Levitin et al., 2005). For example, 85% of individuals with WS display high musical creativity and high emotional reactivity to music, not to mention perfect and relative pitch (Lenhoff, 1998), compared with mental age-matched controls (Martens et al., 2008). Other studies have reported performances equivalent to those of chronological and mental age-matched controls on melodies and phrasing, but lower performances on pitch measurements, rhythm, musical interpretation and

directional tone (Deruelle, Schön, Rondan, & Mancini, 2005). These results are corroborated by neuroanatomical data indicating intact limbic brain structures (emotional functions; Reiss et al., 2000), reduced temporal and perisylvian cortical thickness, and activation of the right tonsil (music; Thompson et al., 2005). Individuals with WS therefore appear to have preserved musical ability, despite a certain modularity in this cognitive domain.

Furthermore, studies exploring visual processing have revealed impaired performances on tests featuring visuospatial components (Farran & Jarrold, 2003; Farran, Jarrold, & Gathercole, 2003; Hoffman et al., 2003; Vicari, Bellucci, & Carlesimo, 2003; Farran, 2005; Landau, Hoffman, & Kurz, 2006; Dilks, Landau, & Hoffman, 2008; O'Hearn et al., 2011). Individuals with WS perform similarly to chronological and mental age-matched controls on visual perception tasks (length estimation; Vicari, Bellugi, & Carlesimo, 2006), but less well on spatial tasks. They also perform better on visual imagery tasks than on visuospatial tasks (block tapping, copying, drawing, hierarchical forms and line orientation; Bellugi et al., 2000; Hoffman et al., 2003; Tager-Flusberg et al., 2003; Karmiloff-Smith et al., 2004; Vicari, Bellugi, & Carlesimo, 2006; Landau, 2011).

This visuospatial deficit seems to be related to the development of the spatial lexicon (Bellugi et al., 2000). A dissociation can be observed between impaired visuospatial representations and preserved language skills (Bellugi et al., 2000; Schmitt et al., 2001; Vicari et al., 2003). Despite relatively well preserved linguistic development, studies have shown that the comprehension of individuals with WS and the language (spatial prepositions) they use to describe spatial locations are below the level expected for their intellectual ability (Bellugi et al., 2000; Jarrold, Baddeley, Hewes, & Phillips, 2001; Vicari et al., 2003; Searcy et al., 2004).

In another cognitive domain, namely face processing, individuals with WS appear to have good face recognition, face discrimination, and recall of both familiar and unknown faces, despite their visuospatial deficits (Bellugi et al., 2000; Mervis, Robinson, Bertrand et al., 2000; Grice et al., 2001; Karmiloff-Smith, Brown, Grice & Paterson, 2003; Carrasco et al., 2005; Farran & Jarrold, 2003; Tager-Flusberg, Plesa-Skwerer, Faja, & Joseph, 2003; Karmiloff-Smith et al., 2004; Martens et al., 2008; O'Hearn et al., 2009). Researchers have investigated the visuoconstructive skills of individuals with WS in order to better understand the atypical cognitive processes involved in face processing (Bellugi et al., 2000). Results indicate that individuals with WS are better able to extract the characteristics of human faces than those of geometric forms (Farran, 2005; Reiss et al., 2005; Porter & Coltheart, 2006; Atkinson et al., 2006; Landau et al., 2006; Musolino & Landau, 2010). For example, individuals with WS display deficits in judgement of line orientation and localization tasks, but not in face recognition (Bellugi et al., 2000). However, these studies suggest that the presence of hair on these faces could facilitate face recognition processes in individuals with WS. It should be noted that in neuroimaging, no difference is observed in the behavior of individuals with WS performing recognition versus localization tasks (Meyer-Lindenberg, Mervis, & Berman, 2006). Research therefore points to incomplete modularization or another specific form of face processing in people with WS (Grice et al., 2001; Martens et al., 2008).

A specific form of face processing does indeed seem to take place in people with WS. Studies have revealed the use of mainly componential (local) processes in face processing/recognition, whereas controls favor global processes (Farran, 2005; Reiss et al., 2005; Atkinson et al., 2006; Landau et al., 2006; Porter & Coltheart, 2006; Musolino & Landau, 2010). A bias toward global rather than local processing of the information therefore appears to be involved in the visuospatial deficits (visuomotor integration, copy tests) observed in

individuals with WS (Bellugi et al., 2000; Farran & Jarrold, 2003; Fayasse & Thibaut, 2003; Martens et al., 2008; Majerus et al., 2010). More specifically, studies suggest difficulty alternating between the underlying global and local processing strategies (Mervis & Klein-Tasman, 2000; Meyer-Lindenberg et al., 2004; Porter & Coltheart, 2006). Similar results have been yielded by neuroimaging studies, which have revealed atrophy of the parietal (deterioration of the dorsal stream) and temporal cortices, and deterioration of the dorsal spatial stream (intraparietal sulcus) compared with the ventral visual stream (Boddaert et al., 2006; Eckert et al., 2006; Meyer-Lindenberg, Buckholz et al., 2006; Van Essen et al., 2006; Martens et al., 2008; Sarpal et al., 2008; Eisenberg et al., 2010; O'Hearn et al., 2011; Thomas et al., 2012). It is important to put these results into perspective, as there may be a local bias in tasks involving drawing when these are administered to individuals with WS (Farran & Jarrold, 2003). Furthermore, the latter's performances on low-level perceptual tasks requiring global processing are similar to those of mental age-matched controls (Mervis et al., 1999; Georgopoulos, Georgopoulos, Kuz, & Landau, 2004). From a functional point of view, there is also a deficit in the saccadic eye movements involved in visuospatial processes (Scerif, Cornish, Wilding, Driver, & Karmiloff-Smith, 2004).

ORAL LANGUAGE

The linguistic development of individuals with WS is often claimed in the literature to be largely unimpaired (Karmiloff-Smith et al., 2003; Carrasco et al., 2005). Their language skills certainly seem to be relatively protected (linguistic age: 8-15 years), compared with their other cognitive skills (Bellugi et al., 2000; Porter & Coltheart, 2005; Alloway & Gathercole, 2006; Porter & Coltheart, 2006; Brock, 2007; Martens et al., 2008; Rhodes, Riby, Fraser, & Campbell, 2011a; Rowe & Mervis, 2012). We find the same dissociation in neuroimaging, between the relative preservation of the temporal lobes (oral language) and a deterioration in the parietal and frontal lobes (visuospatial processing, attention, and executive functions; Reiss et al., 2005; Landau et al., 2006; Meyer-Lindenberg, Mervis, & Berman, 2006; Musolino & Landau, 2010). More specifically, there is a dissociation between the relatively preserved level of vocabulary and difficulties in the syntactic, morphosyntactic and lexical-semantic production domains, grammatical understanding, gender agreement, pragmatics, and oral expression among individuals with WS (Karmiloff-Smith et al., 2003; Carrasco et al., 2005). There is now a large body of published research on oral language, and it is possible to distinguish between the different language skills of individuals with WS, by looking at their phonological, syntactic and semantic levels, their pragmatic skills, and their narrative productions.

Early language development seems delayed by approximately 2 years in individuals with WS, compared with their chronological age-matched peers, but follows a similar trajectory to that of their mental age-matched peers (Bellugi et al., 2000; Laing et al., 2002; Martens et al., 2008). One explanation for this delay concerns the beginning of communication. Studies show that they make less use of gestural language (self-referencing behaviors), which is supposed to be a precursor of language development, than mental age-matched controls (Laing et al., 2002). Moreover, individuals with WS exhibit category-specific perception of speech sounds, indicating a possible deficit in early phonological processing (Karmiloff-Smith, Scerif, & Thomas, 2002; Nazzi et al., 2003).

Furthermore, the appearance of first words is delayed (at around 30-40 months) in WS (Martens et al., 2008). Mervis and Robinson (2000) noticed that 2-year-olds with WS exhibit a smaller lexical repertoire and poorer (expressive) vocabulary skills than their chronological age-matched peers. Nevertheless, the lexical store expands at around 11 years and the complexity of the sentences that are produced increases across development (Bellugi et al., 2000; Volterra, Caselli, Capirci, Tonucci, & Vicari, 2003). It should be noted that adults with WS have a higher vocabulary level than their chronological age-matched peers (animal naming tests; Bellugi et al., 2000). The basic morphosyntactic structures develop quickly among individuals with WS (Martens et al., 2008). Moreover, they exhibit metalinguistic abilities even before they have mastered grammar (Bellugi et al., 2000). However, compared with their mental age-matched counterparts, individuals with WS exhibit delays in terms of mean length of utterance (whose articles and prepositions substitution) (Levy, 2004) and the ability to classify objects (Nazzi, Gopnik, & Karmiloff-Smith, 2005). Karmiloff-Smith et al. (1997) suggested that individuals with WS initially lack the semantic information they need to integrate into syntactic processing.

Apart from lagging behind their chronological age-matched peers, individuals with WS appear to display typical development of linguistic skills (Karmiloff-Smith et al., 2003; Martens et al., 2008; Lacroix, Stojanovik, & Lukács, 2009). Research therefore demonstrates that phonology, vocabulary, syntax, morphosyntax and semantics are protected but delayed (Karmiloff-Smith et al., 2003; Alloway & Gathercole, 2006). Young people with WS nevertheless produce more atypical morphosyntactic errors (Martens et al., 2008) and take longer to resolve them (until age 14-16 years) than their mental age-matched peers do (until age 8-9 years; Bellugi et al., 2000). It should be noted that this gap between the appearance and development of language in WS could be explained by an imbalance between phonological and semantic skills, leading to fragile semantic representations (Mervis & Bertrand, 1997). Naming precedes identification in WS (Jarrold et al., 2001), but both skills are delayed with regard to those of chronological and mental age-matched children (Laing, Hulme, Grant, & Karmiloff-Smith, 2001). There therefore seem to be two dissociations in oral and semantic fluencies in WS (Temple, Almazan, & Sherwood, 2002; Vicari, Bates, Caselli, Pasqualetti et al., 2004; Stojanovik, 2006): greater ease performing semantic fluency tasks than naming ones, as mentioned earlier; and an intact computational component (form of linguistic expressions) versus an impaired lexical one (shape and meaning of parts of speech).

Beyond language development, several studies have investigated the lexical and morphological, syntactic and grammatical, semantic and pragmatic skills of individuals with WS (Brock, 2007; Martens et al., 2008). Research on lexical skills indicates that vocabulary (expressive aspect), verbal fluency, and grammatical (oral fluency, irregular form of past tense, plural, word roots/suffixes), syntactic, and semantic skills are relatively protected, albeit delayed (Bellugi et al., 2000; Thomas et al., 2001; Zukowski, 2005; Martens et al., 2008).

At first sight, individuals with WS use more sophisticated words than their chronological age-matched peers (idiomatic and stereotypical linguistic expressions), despite some errors of contextual use (Udwin & Yule, 1991). The grammatical and syntactic abilities of adults with WS seem equivalent to those of mental age-matched individuals (i.e., 5-10 years; Losh, Bellugi, & Anderson, 2001), and poorer than those of chronological age-matched ones (Karmiloff-Smith et al., 1997). Measures of grammar, syntax (grammatical understanding, morphosyntax, gender agreement), more complex semantics (many words produced but not necessarily understood) and pragmatics indicate atypical skills and delays among individuals

with WS (Bellugi et al., 2000; Temple et al., 2002; Vicari et al., 2004; Lacroix & Bernicot, 2006; Stojanovik, 2006). More specifically, just like their mental age-matched peers, they are capable of using a variety of complex grammatical forms (passive, anaphoric and relative sentences, conditional forms, irregular past tense), despite some morphosyntactic errors, during oral production (Bellugi et al., 2000; Mervis & Klein-Tasman, 2000; Karmiloff-Smith et al., 2003; Ring & Clahsen, 2005). Other studies have reported poorer performances than those of mental age-matched controls when it comes to finding complex similarities (semantic cues; Klein & Mervis, 1999; Mervis & Klein-Tasman, 2000).

The narrative productions of individuals with WS are poorer than those of mental age-matched controls on some tests (e.g., sentence-repetition task; Bellugi et al., 2000). Their expressive linguistic skills are better than their receptive ones, even if they spend more time on the pronunciation and articulation of words than their verbal ability-matched peers (around 8 years) do (Bellugi et al., 2000; Losh et al., 2001; Jarrold, Cowan, Hewes, & Riby, 2004b; Stojanovik, 2006). Furthermore, teenagers with WS display preserved affective language (expression and prosody) in their narratives (Losh et al., 2001) despite their difficulty with mutual communication (Stojanovik, 2006).

These results point to heterogeneous oral language development in WS (Temple et al., 2002; Vicari et al., 2004; Porter & Coltheart, 2005; Stojanovik, 2006; Martens et al., 2008). Furthermore, Stojanovik, Perkins, and Howard (2001) have suggested that the language skills of individuals with WS should be regarded as a relative, but not necessarily effective, cognitive strength.

MEMORY ABILITIES

The past few years have witnessed an increase in research on memory in people with WS. More specifically, since the 1990s, there has been a surge of interest in the underlying processes that are necessary for learning. In this section, we review these studies of short-term memory (including working memory) and long-term memory, which show the memory skills of individuals with WS to be fragile and unloss-making (Jarrold et al., 2004b; Martens et al., 2008; Rhodes et al., 2011a).

Early studies focused on short-term memory, neglecting the executive components of working memory. They failed to reach a consensus, mainly because of evaluation differences (Klein & Mervis, 1999; Mervis & Klein-Tasman, 2000). Some studies reported preserved phonological short-term memory in comparison with mental age-matched controls (Bellugi et al., 2000; Mervis & Klein-Tasman, 2000; Jarrold et al., 2001; Laing et al., 2005; Sampaio, Sousa, Fernandez, Henriques, & Goncalves, 2008), while others compared these performances with those of verbal ability-matched controls (Laing et al., 2001; Majerus et al., 2003; Jarrold, Baddeley, Hewes, Leeke, & Phillips, 2004a; Sampaio et al., 2008; Lacroix, Stojanovik, & Lukács, 2009). Individuals with WS appear to have greater short-term memory difficulties for recall (explicit episodic encoding) than for recognition (O'Hearn et al., 2009; Rhodes, Riby, Park, Fraser, & Campbell, 2010) leading to peculiarities in learning information (Baddeley, 2000). Other studies report poorer performances than those of chronological and mental age-matched individuals on spatial (location) as opposed to visual (recognition) short-term memory tasks (Vicari, Bellugi, & Carlesimo, 2006).

As for working memory skills, they seem fragile because of genuine difficulties in data accumulation (Jarrold et al., 2004b; O'Hearn et al., 2009; Menghini et al., 2010; Rhodes et al., 2010). Scores on working memory tasks (digit and word spans) are therefore lower than those of chronological and mental age-matched controls (Vicari, Bellugi, & Carlesimo, 2006).

Furthermore, there are executive dissociations between verbal and nonverbal working memory among individuals with WS. For example, the verbal/spatial dissociation seems to extend to the functioning of working memory. Individuals with WS display executive deficits in both verbal and spatial working memory (manipulating and updating information), associated with preserved short-term maintenance of spatial, but not verbal, information (Menghini et al., 2010; Rhodes et al., 2011a).

Other results point to specific deficits in spatial versus verbal working memory (Alloway & Gathercole, 2006; Vicari, Bellugi, & Carlesimo, 2006; Sampaio et al., 2008; Rhodes et al., 2011a; Rowe & Mervis, 2012). Neuroimaging studies have shown that a deficit in the dorsal stream (parietal regions) is behind the specific impairment of memory for spatial information (Vicari et al., 2003; Sarpal et al., 2008). These spatial specificities seem to be observed in more complex tasks involving high levels of processing and/or of the handling of a large volume of spatial information (O'Hearn et al., 2009; Menghini et al., 2010; Rhodes et al., 2010; Rhodes et al., 2011a).

Another dissociation concerns visual/visuospatial working memory. Individuals with WS exhibit relatively preserved maintenance of visual information (recognition and visual span tests), but a deficit in handling spatial information, or more specifically, connecting visual and spatial information (Corsi Block localization task; Vicari et al., 2003; Vicari, Bellugi, & Carlesimo, 2006; Jarrold, Phillips, & Baddeley, 2007). For example, it has been reported that, compared with mental age-matched individuals, individuals with WS exhibit a general localization deficit, rather than a specific one for face or house identification (Vicari et al., 2003; Meyer-Lindenberg, Mervis, & Berman, 2006; Vicari, Bellugi, & Carlesimo, 2006; Jarrold et al., 2007; Sarpal et al., 2008; Vicari O'Hearn et al., 2009). One possible explanation for the specificities of their visuospatial working memory is that they have a visuospatial sketchpad deficit that is independent of their mental ability (Munir, Cornish, & Wilding, 2000; Jarrold et al., 2007; O'Hearn et al., 2009; Menghini et al., 2010; Rhodes et al., 2010; Rhodes et al., 2011a). Research indicates a possible dissociation between the processes linked to the visuospatial sketchpad, as visual information seems protected, but not spatial information (Benton Facial Recognition Test; Vicari et al., 2003; Kittler, Krinsky-McHale, & Devenny, 2008; Sampaio et al., 2008). For example, it has been suggested that visuospatial working memory tasks may require mental rotation (Luzzatti, Vecchi, Agazzi, Cesa-Bianchi, & Vergani, 1998). Another explanation therefore concerns deficits in mental rotation, rather than visual abilities, in WS.

Numerous studies of WS have focused on one of the most homogeneous cognitive skills, namely phonological memory. Results indicate relative preservation of phonological short-term memory (Majerus et al., 2003; Laing et al., 2005; Porter & Coltheart, 2005; Sampaio et al., 2008; Lacroix, Stojanovik, & Lukács, 2009). Despite the multiplicity of tests used (digit and word span, nonword repetition) the phonological memory performances of individuals with WS are better than those of their mental age-matched peers (Danielsson, Henry, Messer, Carney, & Rönnerberg, 2016). Certain studies indicate poorer performances on phonological memory tasks with regard to a verbal age of 8 years (Jarrold et al., 2004b), contrary to other studies (Majerus et al., 2003). There is a degree of variability in short-term phonological

memory abilities (Mervis & Klein-Tasman, 2000; Jarrold et al., 2004b). One possible explanation is that the articulatory flow is slower (more time needed for subvocal repetition, planning and pausing), which requires information to be retained for longer, and therefore causes difficulties with short-term recall (Jarrold et al., 2004b; Laing et al., 2005). These articulatory specificities may reflect phonological loop deficits (Kittler et al., 2008; Sampaio et al., 2008).

These data suggest that the short-term memory deficits lead to association difficulties during the learning of new information (Baddeley, 2000). We therefore postulate that the link between short-term memory and long-term episodic learning (episodic buffer; Baddeley, 2000) is impaired. The long-term memory weakness is therefore secondary to greater deficits in short-term memory, particularly if long-term compensation strategies are used (Baddeley et al., 2000). Individuals with WS perform more poorly on long-term memory tasks (recall and recognition) than chronological age-matched controls. More specifically, they display a greater deficit on recall tasks than on recognition (Jarrold et al., 2007). For example, findings point to a visual deterioration in long-term memory for delayed recall rather than a recognition difficulty (fewer elements recalled than copied in the Rey-Osterreith Complex Figure test) in WS (Vicari et al., 1996). We also find this verbal/spatial dissociation in long-term memory performances, with the preservation of verbal rather than visuospatial information, in comparison with the performances of mental age-matched controls (Jarrold et al., 2007).

All these results demonstrate that individuals with WS have weaknesses and atypical verbal and nonverbal memory development, with regard to their mental age-matched peers (Jarrold et al., 2007; Vicari, Verucci, & Carlesimo, 2007; Sampaio et al., 2008). Furthermore, their deficits in visuospatial and phonological short-term memory may be secondary to more general problems in visuospatial and phonological processing. In short, some memory deficits seem to be more generally connected to learning difficulties (Jarrold et al., 2007; Kittler et al., 2008).

Furthermore, memory abilities must be studied in relation to executive and attentional functions, as both these areas play a fundamental role in the cognitive and behavioral development of individuals with WS.

EXECUTIVE AND ATTENTIONAL FUNCTIONS

Children with WS exhibit attentional and executive deficits that decrease in adolescence (Farran & Jarrold, 2003; Carrasco et al., 2005; Willcutt, Sonuga-Barke, Nigg, & Sergeant, 2008; Rhodes et al., 2010). Neuroimaging studies show a deficit in the frontal and parietal lobes for particular attentional tasks (Atkinson & Braddick, 2010; Rhodes et al., 2010). More specifically, the performances of individuals with WS on selective, divided and sustained attention tasks are poorer than those of their chronological age-matched peers, but equivalent to those of mental age-matched controls (Farran & Jarrold, 2003; Menghini et al., 2010; Costanzo et al., 2013; Greer, Riby, Hamilton & Riby, 2013). Individuals with WS also perform better on tasks requiring sustained rather than selective attention, compared with their mental age-matched peers (Atkinson & Braddick, 2010).

Furthermore, there seem to be verbal/visuospatial dissociations in selective and sustained attention tasks. For example, individuals with WS perform equally well on both visual sustained

and verbal selective attention tasks, but more poorly compared with chronological or mental age-matched controls (Scerif et al., 2004; Menghini et al., 2010; Costanzo et al., 2013).

More generally, people with WS have deficits in flexibility and attentional set-shifting (pointing/counter-pointing, face fixation) that extend to the visuomotor domain (Mervis, Robinson, Rowe, Becerra, & Klein-Tasman, 2003; Willcutt et al., 2008; Menghini et al., 2010; Rhodes et al., 2010; Hocking et al., 2013). More specifically, individuals with WS have impaired performances on attentional switching tasks (Rhodes et al., 2010). Analysis of these performances has revealed a dissociation whereby verbal performances are better than visuospatial ones (Carney, Brown & Henry, 2013; Menghini et al., 2010). One possible explanation is an inhibition deficit in verbal skills (Davidson, Amso, Anderson, & Diamond, 2006).

The executive function planning is also impaired in individuals with WS, compared with chronological and mental age-matched controls (Vicari, Bellugi, & Carlesimo, 2006; Willcutt et al., 2008; Menghini et al., 2010; Rhodes et al., 2010; Cowie, Braddick & Atkinson, 2012; Costanzo et al., 2013; Greer et al., 2013). These results have been confirmed by neuroimaging studies showing a deficit in the dorsal and frontoparietal circuits involved in planning, motor execution, and inhibition (Campbell et al., 2009; Faria et al., 2011). However, when individuals with WS are given more time to specify their answers, their planning performances seem relatively protected (Rhodes et al., 2010; Menghini et al., 2010). This points to cognitive slowing rather than an executive deficit in WS.

Inhibition functions are impaired in individuals with WS (Vicari, Bellugi, & Carlesimo, 2006; Jarrold et al., 2007; Porter, Coltheart, & Langdon, 2007; Kittler et al., 2008; Sampaio et al., 2008; O'Hearn et al., 2009; Menghini et al., 2010; Rhodes et al., 2010; Osório et al., 2012; Costanzo et al., 2013; Hocking et al., 2013). Individuals with WS take longer and make more errors (inhibition deficits) than chronological or mental age-matched controls (Greer et al., 2013). More specifically, individuals with WS exhibit poorer visual inhibition in the visuospatial domain (Costanzo et al., 2013). Carney, Brown, and Henry (2013) observed poorer performances compared with those of chronological and mental age-matched participants. Neuroimaging studies indicate deficits in the frontal lobe and frontostriatal networks that could account for failures in the inhibition process and thus for inappropriate social behaviors (hypersociability, social disinhibition, and emotional problems; Porter et al., 2007; Rhodes et al., 2010; Rhodes, Riby, Matthews, & Coghill, 2011b; Greer et al., 2013; Hocking et al., 2013; Little et al., 2013).

Compared with chronological age-matched controls, individuals with WS therefore display deficits in a range of executive functions (attention, memory, problem solving, planning and inhibition; Vicari, Bellugi, & Carlesimo, 2006; Jarrold et al., 2007; Porter et al., 2007; Kittler et al., 2008; Sampaio et al., 2008; Willcutt et al., 2008; O'Hearn et al., 2009; Lanfranchi, Jerman, Dal Pont, Alberti, & Vianello, 2010; Rhodes et al., 2010; Osório et al., 2012). These executive deficits may also contribute to the social phenotype (behavior and adaptive functioning), resulting in hypersociability, inattention, distractibility, low frustration threshold, anxiety, and poor social understanding (Carrasco et al., 2005; Meyer-Lindenberg, Mervis, & Berman, 2006; Martens et al., 2008; Willcutt et al., 2008; Campbell et al., 2009; Martens, Wilson, Dudgeon, & Reutens, 2009; Menghini et al., 2010; Rhodes et al., 2010; Faria et al., 2011; Rhodes et al., 2011b; Meda, Pryweller & Thornton-Wells, 2012; Greer et al., 2013). Howlin and colleagues (1998) found that adults with WS (mean age = 27 years) exhibit socio-adaptive behavior equivalent to that of 6-year-olds. Neuroimaging studies indicate differences

in the left temporal lobe (hyperactivity; Campbell et al., 2009) and a deficit in the frontal and parietal lobes (hypersociability) among children with WS (Thompson et al., 2005; Boddaert et al., 2006; Eckert et al., 2006; Campbell et al., 2009; Faria et al., 2011; Osório et al., 2012).

These results underscore the importance of examining interdomain interactions from a developmental point of view, as cognitive strengths and weaknesses beyond the domain of interest can have a considerable impact on the behavioral phenotype (Karmiloff-Smith, 2009; Karmiloff-Smith, 2012).

DISCUSSION AND PERSPECTIVES

Approximately 95% of individuals with WS display considerable learning difficulties (Paterson, Girelli, Butterworth, & Karmiloff-Smith, 2006). However, despite their intellectual deficiency and neuropsychological profile, individuals with WS appear to be capable of learning more than the basic skills of reading, spelling and mathematics at school (Howlin et al., 1998; Bellugi et al., 2000). For example, those aged between 6 and 16 years have the reading, spelling, arithmetic and social adaptation levels of 6- to 8-year-olds (Howlin et al., 1998; Bellugi et al., 2000).

None of these studies simultaneously considered all the cognitive processes underlying the unique neuropsychological profile responsible for these learning difficulties. Instead, most focused on two or three cognitive-behavioral or neuroanatomical features. In this chapter, we have therefore tried to provide an overview of the specific neuropsychological profile of individuals with WS, which might explain their learning difficulties. Although they exhibit considerable heterogeneity in the cognitive, linguistic, perceptual, memory and executive functions involved in the behavioral phenotypes (Majerus et al., 2001; Majerus et al., 2003; Porter & Coltheart, 2005), we can nevertheless identify universal cognitive characteristics

At the cognitive level, the development of cognitive functions seems typical, albeit delayed, in WS (Majerus et al., 2001; Porter & Coltheart, 2005). The study by Bellugi, Lichtenberger, Jones, Lai, and St. George (2000) was the first to establish clear dissociations in the cognitive architecture of individuals with WS. Certain skills seem relatively protected (oral language, lexical level, short-term memory, face processing) while others seem impaired (visuospatial processing, planning, inhibition, attention, long-term and working memory; Fayasse & Thibaut, 2003; Karmiloff-Smith et al., 2003; Martens et al., 2008; Menghini et al., 2010; Costanzo et al., 2013; Dessalegn et al., 2013). Several explanations have been put forward for these deficits, which include a linguistic imbalance between semantics and phonology leading to poor semantic representations (Laing et al., 2002; Nazzi et al., 2003), the use of local rather than overall processing of visuospatial information and difficulty alternating between strategies (Meyer-Lindenberg, Mervis, & Berman, 2006; Porter & Coltheart, 2006; Dessalegn et al., 2013), working memory deficits concerning the visuospatial sketchpad and/or phonological loop (Kittler et al., 2008; Sampaio et al., 2008; O'Hearn et al., 2009; Menghini et al., 2010; Rhodes et al., 2010; Rhodes et al., 2011a), and deficits in the dorsal frontoparietal circuit involved in inhibition, planning and social behavior (Campbell et al., 2009; Rhodes et al., 2011b; Faria, Landau, O'Hearn, et al., 2012; Hocking et al., 2013; Greer et al., 2013; Little et al., 2013). However, the results of some studies suggest that these dissociative profiles are not perceptible in all individuals with WS (Porter & Coltheart, 2005; Vicari, Bellugi, &

Carlesimo, 2006; Sampaio et al., 2008; Rhodes et al., 2011a). This heterogeneity of results may stem from experimental artefacts (use of different tools), but may also reveal the existence of developmental subprofiles.

At the experimental level, there seem to be disparities in results depending on the test, control group, age range, size and developmental specificities of the sample (Vicari, Bellugi, & Carlesimo, 2006; Jarrold et al., 2007; Van der Molen, Van Luit, Jongmans, & Van der Molen, 2007; Martens et al., 2008; Sampaio et al., 2008; Schuchardt, Mäehler, & Hasselhorn, 2011; Greer et al., 2013). For example, floor and ceiling effects have been found for visuospatial processing, depending on the choice of test and type of control (e.g., mental, chronological, verbal or vocabulary age-matched, other pathologies; Farran & Jarrold, 2003). Some studies that did not include a control group based on verbal ability have reported good performances on verbal memory (Sampaio et al., 2008), in contrast to other studies (Jarrold et al., 2004a). Furthermore, 68% of the studies of language or visuospatial skills included samples that varied from 1 to 54 individuals with WS (Martens et al., 2008).

At the behavioral level, a direct window on the initial state (Karmiloff-Smith, 1998), individuals with WS exhibit hypersociability, hypersensitivity, anxiety, specific phobias and socially inappropriate language (Martens et al., 2008; Carrasco et al., 2005). These behavioral characteristics seem to persist with age (Dykens, 2003; Rosner, Hodapp, Fidler, Sagun, & Dykens, 2004). However, this behavioral change in individuals with WS seems to take place later than it does in controls (see research on depression: Meyer-Lindenberg, Mervis, & Berman, 2006). It should be noted that most behavioral research has used two types of assessment: self-report questionnaire and/or parental questionnaire. It is thus advisable to temper results on hyperactivity, anxiety and attentional difficulties among individuals with WS and/or parental fears (Dykens, 2003) owing to potential biases.

At the neuroanatomical and functional levels, results clarify the specificities of the cognitive profile. Limbic structures (hypersensitivity) are preserved (Reiss et al., 2000), as is the lower temporal lobe and the activation of the right tonsil (language and music) (Thompson et al., 2005), but there are deficits in the intraparietal/occipitoparietal sulcus (visuospatial deficits and hypersociability), and reduced connectivity between the tonsil and orbitofrontal cortex (hypersociability and anxiety) (Van Essen et al., 2006; Marenco et al., 2007; Dilks et al., 2008; Sarpal et al., 2008; O'Hearn et al., 2009; Faria et al., 2011).

All these results therefore suggest that there is a specific and heterogeneous cognitive pattern in WS. This cognitive specificity seems stable across development (Karmiloff-Smith & al., 2002; Dykens, 2003; Rosner et al., 2004). Moreover, the numerous cognitive dissociations may explain this considerable heterogeneity. It is therefore important to understand the trajectories of developmental disorders better by favoring longitudinal studies (Karmiloff-Smith et al., 2002). We dispute the usefulness of nativist hypotheses or modular continuity for estimating cognitive profiles from adult models, that is, without studying developmental trajectories (Karmiloff-Smith et al., 2002). For example, comparisons of individuals with WS versus Down syndrome (DS) reveal different cognitive profiles in adulthood, despite resemblances during development (Klein & Mervis, 1999).

Intersyndrome comparisons can improve current understanding of the cognitive specificities of individuals with WS. For example, studies indicate similar IQ scores across WS and DS (Klein & Mervis, 1999; Mervis & Klein-Tasman, 2000), and show that good face processing skills are not specific to individuals with WS. They report similar abilities to distinguish between faces across WS and other types of intellectual deficiency or learning

disorder (Tager-Flusberg & Sullivan, 2000; Martens et al., 2008). By contrast, good verbal abilities and verbal working memory seem to be specific to WS. Several studies indicate better verbal skills (vocabulary and grammar) in WS compared with DS for the same vocabularylexicon age?? and mental ages (Bellugi et al., 2000) or children with a mental retardation of mixed etiology or a learning disorder (Udwin & Yule, 1991). Moreover, verbal working memory skills (digit and word spans) are better in WS than in DS (Klein & Mervis, 1999; Edgin, Pennington, & Mervis, 2010) but equivalent in disorders of mixed etiology (Devenny, Krinsky-McHale, Kittler, et al., 2004). It should be noted that we find this dissociation between the verbal and visuospatial domains. data indicate lower spatial associative and short-term memory performances in WS than in DS (Klein & Mervis, 1999). Finally, we can put the visuo-spatial deficits displayed by individuals with WS into perspective: performances on visuospatial tasks are better in WS than in learning disorders (Udwin & Yule, 1991) or DS (Klein & Mervis, 1999).

Studying atypical populations such as individuals with WS allows us to gain a better understanding of typical learning development. If we are to provide appropriate treatment, it is vital that we identify the cognitive specificities of individuals with WS and their developmental trajectory. Questions about the adaptability of tests to individuals with intellectual deficiency, the processes that are studied, and the generalization of the results require particular attention. For instance, results can only be generalized if the sample size is sufficiently large and there is a reasonable age range between the participants. It is also crucial to take account of the trajectory and developmental specificities of samples with neurodevelopmental disorders, such as participants with WS (Karmiloff-Smith, 1998). Longitudinal studies of individuals with WS are therefore needed in order to carry out a more thorough examination of their relatively typical cognitive abilities, albeit delayed with regard to controls (Karmiloff-Smith et al., 2002; Martens et al., 2008).

Chapter 71

PREIMPLANTATION GENETIC DIAGNOSIS (PGD) FOR CHROMOSOME REARRANGEMENTS

Chun Kyu Lim

Laboratory of Reproductive Medicine, Cheil General Hospital and Women's Healthcare
Center, Dankook University College of Medicine, Seoul, South Korea

INTRODUCTION

Chromosome rearrangements are the most common genetic abnormalities in humans. Abnormal chromosomal configurations are formed among non-homologous chromosomes to allow full synapsis of homologous chromosomes at meiosis I of chromosome rearrangement carriers. These abnormal chromosomal configurations result in the production of gametes with various chromosomal complements due to malsegregation of derivative chromosomes or recombination. Most of the gametes have unbalanced chromosomal complements and only a small number of gametes have normal or balanced chromosomal complements. Carriers of balanced chromosome rearrangements are phenotypically normal but they are at an increased risk of abnormal pregnancies due to the unbalanced gametes. However, chromosome rearrangement carriers who cannot have babies or experience repeated abortions or abnormal pregnancies can have healthy babies after introduction of PGD. Balanced reciprocal translocation is the most common chromosome rearrangement. Thirty-two types of gametes can be produced in meiosis of reciprocal translocation carrier. According to the results that analyze the meiotic segregation of embryos from PGD cycles of reciprocal translocation carriers, 2:2 segregation is the main segregation mode. The meiotic segregation might be affected by the gender of carriers. The frequency of balanced embryos was not different between female and male carriers. However, the frequencies of 2:2 segregation, especially adjacent-1 segregation, 3:1 and 4:0 segregation were significantly different between female and male carriers. Robertsonian translocation is also common chromosome rearrangement in humans. Gametes with eight different chromosomal complements can be produced in Robertsonian translocation carriers. The frequency of balanced embryos was higher in male carriers than in female carriers. Carriers of complex chromosome rearrangements (CCR), very rare chromosome rearrangements, can achieve pregnancy by PGD although the number of

normal or balanced embryos was extremely low. Although it is very difficult to estimate the rate of normal or balanced embryos, the rate is estimated to be less than 10% in PGD for CCR carriers. The 3:3 segregation and chaotic segregation (meiotic segregation whose meiotic segregation cannot be defined) are prevalent segregation modes in carriers of three-way translocation. In PGD cycles of CCR carriers, cycle cancellation is very frequent due to the absence of the normal or balanced embryos. Therefore, it is important that a large number of embryos are obtained in one cycle. Occasionally, abnormalities of chromosome rearrangement-unrelated chromosomes are observed in embryos or abortuses although chromosome rearrangement-related chromosomes are normal or balanced. At present, PGD that diagnose all 24 chromosomes using array-CGH, SNP array or NGS is carried out worldwide. In those PGD cycles, the risk that embryo transfer is cancelled might be increased. However, the rate of normal or balanced embryos is unexpectedly increased and pregnancy rate is improved. Surely, PGD is the very effective assisted reproductive technique in achieving pregnancy of chromosome rearrangement carriers by preventing repeated abortions that chromosome rearrangement carriers usually experience. In the field of PGD for chromosome rearrangements, the next stage will be the development of technique that can discriminate between normal embryos and balanced embryos.

Chromosome rearrangements, such as translocation (reciprocal or Robertsonian), inversion and complex chromosome rearrangements, are the most common genetic abnormalities in humans. Chromosome rearrangements are classified as balanced or unbalanced (Nussbaum et al., 2016). Carriers of balanced chromosome rearrangements have the normal chromosomal complements but carriers of unbalanced chromosome rearrangements have additional or missing chromosomal material. Generally, the incidence of balanced chromosome rearrangements is about 0.19% of newborns (Jacobs, et al., 1974; Hamerton, et al., 1975). Carriers of balanced chromosome rearrangements are phenotypically normal because they have all the genetic materials. However, they are at an increased risk of implantation failure, repeated abortions or birth of chromosomally unbalanced offspring. Of course, not all carriers of balanced chromosome rearrangements experience the abnormal pregnancies. The abnormal pregnancies are resulted from the unbalanced gametes generated during meiosis of chromosome rearrangement carriers. Abnormal chromosomal configurations are formed to allow full synapses of homologous chromosomes during meiosis of balanced chromosome rearrangement carriers. The unbalanced gametes are produced as a results of malsegregation of these abnormal chromosomal configuration. Most of the gametes produced during meiosis of chromosome rearrangement carriers have unbalanced chromosomal complements. These unbalanced gametes result in implantation failure, repeated abortions or birth of chromosomally unbalanced offspring.

After the first successful clinical application of preimplantation genetic diagnosis (PGD) in 1990 (Handyside et al., 1990), PGD has been widely used worldwide to select normal or balanced embryos in *in vitro* fertilization and embryo transfer (IVF-ET) programs of balanced chromosome rearrangement carriers. Cleavage-stage fluorescence in situ hybridization (FISH) has been widely used to PGD for carriers of balanced chromosome rearrangements till the early 2010s (Van Assche, et al. 1999; Otani, et al. 2006; Bernicot, et al. 2012; Ko, et al. 2013) and PGD based on array comparative genomic hybridization (CGH) (Alfarawati, et al. 2011; Fiorentino, et al., 2011; Colls, et al. 2012; Huang, et al. 2013; Tan, et al. 2013) or next generation sequencing (NGS) (Fiorentino, et al. 2014a, b; Huang, et al. 2014; Wells, et al. 2014; Tan et al., 2014; Lukaszuk et al., 2015) is widely applied nowadays. The only abnormalities of

rearranged chromosomes can be diagnosed in FISH-based PGD and the abnormalities of other chromosomes cannot be diagnosed. However, abnormalities of all 24 chromosomes can be diagnosed after the application of array CGH or NGS into PGD.

EMBRYO BIOPSY

To perform PGD, one cell or a few cells have to be removed from oocytes or embryos. Cells necessary for PGD can be removed at three different stages, polar body from the oocytes and/or the zygotes, one or two blastomeres from cleavage stage embryos or trophectoderm (TE) from the blastocysts. Embryo biopsy is mainly performed at cleavage stage but trophectoderm biopsy is gradually increasing these days (Moutou et al., 2014; Cimadomo et al., 2016).

A small hole has to be made within the zona pellucid to remove polar body or blastomere(s). This zona breaching can be conducted by one of following methods; mechanical, laser-assisted or acidified Tyrode's drilling methods. Recently, laser-assisted zona breaching is most popularly used (Moutou et al., 2014). Clinical outcomes are not different among these three methods (De Vos and Van Steirteghem, 2001; Jones et al., 2006; Geber et al., 2011; Eldar-Geva et al., 2014).

Cleavage stage biopsy is performed on day 3 embryos. One or two blastomeres with one distinct nucleus are removed from embryos with at least 6 cells. Blastomere biopsy is usually conducted in $\text{Ca}^{2+}/\text{Mg}^{2+}$ -free medium in order to facilitate removal of blastomere from embryos. However, there are controversies about the effect of Ca^{2+} depletion on embryo development (Sefton et al., 1996; Dumoulin et al., 1998; Pey et al., 1998). Preimplantation embryos show high chromosomal mosaicism and some of these embryos can develop to blastocysts (Wells and Delhanty, 2000; Bielanska et al., 2002). Embryonic mosaicism cannot be identified by single-blastomere biopsy. Therefore, two-blastomere biopsy can be performed to compensate the problems caused by single-blastomere biopsy. However, embryonic development can be affected by two-blastomere biopsy because too much embryonic mass is removed from embryos (Cohen et al., 2007). ESHRE guidelines suggested that two-blastomere biopsy could be safely applied to PGD when embryos with ≥ 6 cells and $\leq 30\%$ of fragmentation (Goosens et al., 2008).

Polar body biopsy can be performed as an alternative to blastomere biopsy. In some countries, polar body biopsy is mainly performed since blastomere biopsy is legally prohibited. Zona breaching is performed with the same method as blastomere biopsy. Chromosomal abnormalities from mitotic errors or paternally derived aneuploidies cannot be detected when polar body biopsy is adopted. Nowadays the use of polar biopsy is decreasing.

Blastocyst stage preimplantation genetic screening (PGS) is emerging as the most promising approach to select euploid embryos. Several cells (five to ten cells) are removed from the blastocyst on day 5 or 6. PGD coupled with blastocyst biopsy is barely affected by biopsy operators (Capalbo et al., 2015) and embryonic mosaicism that is common in preimplantation embryos, because PGD is carried out using several cells. Therefore, the application of blastocyst biopsy is increasing and gradually replacing both polar body biopsy and blastomere biopsy. One of two different blastocyst biopsy methods is carried out currently. The first method is that a few cells herniated from blastocyst are removed using laser on day 5 or 6 through the small hole that is made in the zona pellucid on day 3 (McArthur et al., 2005).

Embryonic development might be affected by zona breaching and some of inner cell mass (ICM) may be biopsied together with trophoctoderm cells because the position that ICM is formed is unpredictable. The second method is that TE cells are removed simultaneously with zona breaching on day 5 or 6 (Capalbo et al., 2014). According to this method, only TE cells can be isolated from blastocyst and embryonic development is not disturbed since the biopsy operator can choose the site of biopsy. However, high standards of embryo culture and cryopreservation techniques have to be established for blastocyst biopsy to be carried out.

PREGNANCY HISTORY OF CHROMOSOME REARRANGEMENT CARRIERS

In general, chromosome rearrangement carriers have poor pregnancy history before PGD. They spend several years (mean of 3.2 years) to have a baby (Chang et al., 2012). And most of them experienced repeated miscarriages or live births of babies with multiple congenital anomalies due to unbalanced karyotypes. More than 90% of spontaneous pregnancies resulted in miscarriages (Munne et al., 2000a; Lim et al. 2008a; Keymolen et al., 2012; Liao et al., 2014). Most couples with chromosome rearrangements choose PGD to overcome the repeated miscarriage and have healthy babies. Actually, miscarriage rate decrease significantly when they become pregnant after PGD. Therefore, PGD can be a useful option that chromosome rearrangement carriers can choose to have healthy babies (Munne et al. 2000a; Lim et al., 2004).

PGD FOR BALANCED RECIPROCAL TRANSLOCATION

Balanced reciprocal translocation is the most common structural abnormalities of chromosomes with an incidence of about 0.16% in livebirth (Van Dyke et al., 1983). The risk that reciprocal carriers conceive a chromosomally abnormal embryo varies from 20% to 80%, depending on types of translocation, chromosomes involved in the translocation, position of the breakpoints, and gender of the carrier (Goldman and Hulten, 1993; Martin and Hulten, 1993). However, the risk of abnormal pregnancy or pregnancy loss can reduced by PGD in reciprocal translocation carriers (Munne et al., 2000a, 2002; Lim et al., 2004; Grace et al., 2006). During meiosis I of reciprocal translocation carriers, a quadrivalent is formed to make synapses between homologous chromosomes. And then, the quadrivalent segregate according to one of five segregation modes; 2:2 segregation (alternate, adjacent-1 and adjacent-2), 3:1 segregation and 4:0 segregation. Crossing-over between the centromere and the breakpoint or anaphase II non-disjunction result in gametes with unbalanced chromosomal complements. In theory, thirty-two different gametes with different chromosome complements can be generated at the end of meiosis I (Scriven et al., 1998). Only two among the gametes have normal chromosomal complements and the other gametes have partial aneuploidy. Uncommon viable conceptuses with abnormal chromosomal complement can be resulted from the gametes with partial aneuploidy.

Table 1. PGD outcomes of reciprocal translocation carriers

References	Biopsy stage	% of normal or balanced embryos	% of clinical pregnancy	% of abnormal pregnancy*	% of ET cancel**	PGD techniques

* Percent per embryos transfer.

** Embryo transfer was canceled because of the absence of normal/balanced embryos or insufficient quality of embryos for transfer.

Reciprocal translocation carrier couples can achieve successful pregnancies through PGD and the pregnancy rate of them is comparable to that of couples with normal karyotype. PGD results can be obtained in more than 90% of diagnosed embryos and about 11 ~ 45% of the embryos are identified as normal or balanced and transferable embryos (Table 1). Biopsy stage of embryos can affect the rate of normal or balanced embryos. The rate of normal or balanced embryos is higher when embryos are biopsied at blastocyst stage than cleavage stage (Xiong et al., 2014; Tobler et al., 2014; Idowu et al., 2015). Compared to blastomere biopsy, the fewer embryos are available for biopsy in blastocyst biopsy. The unbalanced embryos can develop to the blastocyst stage but it seems that the developmental potential of unbalanced embryos is inferior to that of balanced embryos. Therefore, the rate of normal or balanced embryos is higher when biopsy is carried out in blastocysts (Tan et al., 2013).

Embryo transfers are occasionally cancelled due to the absence of normal or balanced embryos in several cycles, ranging from 9.3 to 51.3% of started cycles. The main reason for the absence of normal or balanced embryos is that the number of embryos available for PGD is small. Although rare, embryo transfer might be cancelled due to the absence of normal or balanced embryos when a large number of embryos are available for PGD. And among pregnancies achieved by PGD, several pregnancies are aborted within the first trimester of

gestation. Aneuploidies of translocation-unrelated chromosomes are frequently observed in embryos or abortuses. Aneuploidies of translocation-unrelated chromosomes are observed in 12 ~ 26% of diagnosed embryos (Xiong et al., 2014; Idwou et al., 2015). It is known that the incidence of aneuploidy or mosaicism is very high in human preimplantation embryos. Chromosomal aneuploidy is increased in translocation carriers (Blanco et al., 2000; Morel et al., 2001; Oliver-Bonet et al., 2001) and about 50% of the embryos diagnosed as normal-balanced are aneuploid (Pujol et al., 2006). It has been suggested that translocations might disturb the meiotic disjunction of the translocation-unrelated chromosome pairs resulting in non-disjunction. Diagnoses for translocation-unrelated chromosomes are not possible when PGD for chromosome rearrangement is performed using FISH. However, abnormalities of translocation-unrelated chromosomes can be diagnosed since PGD for 24 chromosomes using array CGH or NGS is currently performed (Xiong et al., 2014; Tan et al., 2014; Idwou et al., 2015; Gui et al. 2016). PGD for 24 chromosomes has the merit of diagnosing aneuploidies of translocation-unrelated chromosomes together with translocation-related chromosomes. However, at the same time, the risk of embryo transfer cancellation is high due to the aneuploidies of translocation-unrelated chromosomes (Fiorentino et al., 2011; Tan et al., 2013; Xiong et al., 2014).

According to meiotic segregation analysis of embryos from reciprocal translocation carriers, 2:2 segregation is the most prevalent segregation mode. The 2:2 segregation is identified in more than half of the embryos from reciprocal translocation carriers (Scriven et al., 2000; Lim et al., 2008a; Ko et al., 2010). Among 2:2 segregation modes, the incidence of alternate segregation is similar that of adjacent-1 segregation and the incidence of adjacent-2 segregation is lower than that of alternate or adjacent-1 segregation. The incidence of 3:1 segregation mode is similar to that of alternate or adjacent-1 segregation and 4:0 segregation is observed although the frequency is low. And meiotic segregation cannot be determined in about 15% of diagnosed embryos. Meiotic segregation can be affected by gender of carrier, translocation-related chromosomes or the location of breakpoint. The frequency of normal or balanced embryos is not different between male and female carriers. However, the incidences of each segregation mode are significantly different between male and female carriers. The incidence of 2:2 segregation, especially adjacent-1 segregation, is higher in male carriers (60.8% vs. 52.7%, $P < 0.05$) and the incidences of 3:1 segregation or 4:0 segregation are significantly higher ($P < 0.05$) in female carriers (28.4% vs. 20.5% and 3.2% vs. 1.6%, respectively) (Ko et al., 2010). The incidence of alternate segregation is low when acrocentric chromosomes (chromosome 13, 14, 15, 21 or 22) are involved in translocation (Lim et al., 2008; Ye et al., 2012). And the incidence of normal or balanced embryos is lower in translocation carriers who have terminal breakpoint than carriers whose breakpoint is not terminal (Ye et al., 2012). It is known that the acrocentric chromosomes are less stable during meiosis or mitosis than metacentric or submetacentric chromosomes. During meiosis, translocated acrocentric chromosomes may not form a typical quadrivalent as observed in reciprocal translocations between metacentric and/or submetacentric chromosomes. This phenomenon may be related to predisposing of adjacent-2 or 3:1 segregation (Jalbert and Sele, 1979).

PGD FOR ROBERTSONIAN TRANSLOCATION

Centric fusion of two acrocentric chromosomes results in Robertsonian translocation, which is one of the most common chromosomal rearrangements (Nielsen and Wohler, 1991). Like balanced reciprocal translocation carriers, Robertsonian translocation carriers are phenotypically normal but they are also at an increased risk of chromosomally abnormal pregnancies (Scriven et al., 1998). Robertsonian translocation carriers who experienced repeated abortions or birth of babies with congenital anomalies or mental retardations can achieve normal pregnancy by PGD (Munne et al., 1998; Fischer et al., 2010). During meiosis of Robertsonian translocation carriers, trivalent is formed and gametes with eight different chromosomal complements are produced. Only two gametes produced by alternate segregation have normal or balanced chromosomal complements and the others have unbalanced chromosomal complements.

Pregnancy outcome of Robertsonian translocation carriers is similar to that of balanced reciprocal translocation carriers. More than 90% of biopsied embryos are diagnosed successfully and about 30 ~ 50% of diagnosed embryos are available to embryo transfer (Table 2). The rate of transferable embryos is higher in male carriers than in female carriers (Ko et al., 2013; De Rycke et al., 2015). Embryo transfer is cancelled due to the absence of normal or balanced embryos in 10~30% of oocyte retrieval cycles. Similar to reciprocal translocation carriers, several pregnancies after PGD are aborted within the first trimester of gestation. However, miscarriage rate is significantly lower after PGD than before PGD. Various karyotypes are observed in the cytogenetic analysis results of the abortuses: normal, balanced karyotype or aneuploidies of translocation-unrelated chromosomes.

* Percent per embryos transfer.

** Embryo transfer was canceled because of the absence of normal/balanced embryos or insufficient quality of embryos for transfer.

Alternate or adjacent segregation are the dominant segregation modes according to meiotic segregation analysis of embryos from PGD for Robertsonian translocation carriers. There are some differences in segregation patterns between female and male carriers (Munne et al., 2000b; Ko et al., 2013). The rate of embryos from alternate segregation is significantly higher in male than in female carriers (43.9% vs. 29.9%, $P < 0.01$) and the rate of embryos whose meiotic segregation cannot be determined is significantly higher in female than male carriers (15.8% vs. 8.9%, $P < 0.01$). In (13;14) translocation carriers, the most common Robertsonian translocation, the rate of embryos from alternate embryos is significantly higher in male than in female carriers (44.0% vs. 29.2%, $P < 0.01$) and the rate of embryos from adjacent segregation is significantly higher in female than male carriers (47.9% vs. 37.1%, $P < 0.01$). However, the information on meiotic segregation of Robertsonian translocation carriers, especially female carriers, is insufficient. More studies are needed. Aneuploidies of translocation-unrelated chromosomes might increase in unbalanced embryos. In Robertsonian translocation carriers, aneuploidies of chromosome 18 is significantly higher ($P < 0.001$) in embryos from 3:0 segregation or embryos whose meiotic segregation cannot be determined (chaotic segregation) than in embryos from 2:1 segregation (alternate segregation or adjacent segregation) (Ko et al., 2013). Among embryos whose translocation-related chromosomes are diagnosed as normal or balanced, several embryos cannot be transferred due to aneuploidies of chromosome 18. It is not known what cause the increase of chromosome 18 aneuploidy in embryos from 3:0 or chaotic segregation. However, in those embryos, factors that cause malsegregation of translocation-related chromosomes seem to increase aneuploidy of chromosome 18 and these factors need to be identified. Nowadays, aneuploidies of translocation-unrelated chromosomes can be diagnosed concurrently together with abnormalities of translocation-related chromosomes. In PGD cycles of Robertsonian translocation carriers where 24 chromosomes are diagnosed, a high clinical pregnancy rate (83.3%) and implantation rate (66.7%) are achieved in carriers of Robertsonian translocation (Fiorentino et al., 2011). However, aneuploidies of translocation-unrelated chromosomes are observed in more than half of the normal or balanced embryos (Fiorentino et al., 2011; Rius et al., 2011). Therefore, the number of transferable embryos might be decreased in those PGD cycles.

PGD FOR COMPLEX CHROMOSOME REARRANGEMENT (CCR)

Complex chromosome rearrangements (CCRs) are very rare events in human. CCRs are generally defined as balanced or unbalanced structural chromosomal abnormalities involving more than two breakpoints and a simple exchange of genetic material between two chromosomes (Pai et al., 1980). Most familial CCRs are of maternal origin (Batista et al., 1994; Madan et al., 1997) and most *de novo* CCRs are of paternal origin (Batista et al., 1993, 1994). There are few studies on the incidence of CCRs in the general population. However, the incidence of CCRs has been estimated to be around 0.1% among infertile individuals (Mau-Holzmann, 2005). Like other chromosome rearrangement carriers, CCR carriers are also phenotypically normal. However, they are estimated to have a 50% risk of miscarriage and a 20% risk of having a child with an unbalanced karyotype (Gorski et al., 1988; Madan et al., 1997). However, these figures cannot be applied to individual CCR carriers as a wide variety

of gametes can be produced depending on the number of chromosomes and the number of breakpoints involved in CCRs (Kausch et al., 1988; Loup et al., 2010). The risk of phenotype abnormality increases with the number of chromosomes and the number of breakpoints involved in CCRs (Ruiz et al., 1996; Madan et al., 1997; Giardino et al., 2006). Estimating risk for spontaneous abortions or phenotypic abnormalities of CCR carriers is very difficult and remain empirical, ranging from 50 to 100% for spontaneous abortion (Batista et al., 1994) and from 20 to 90% for phenotypic abnormalities (Gorski et al., 1988). Analyses of meiotic segregation of CCRs are also very difficult due to the nature of CCRs and the number of chromosomes involved in CCRs. An abnormal configuration of chromosomes is formed during meiosis I of CCR carriers. The abnormal configuration causes either malsegregation of derivative chromosomes or generation of a recombinant chromosome (Pellestor et al., 2011b). For example, a hexavalent configuration is formed to allow full synapses of homologous segments during meiosis of three-way translocation, the most common type of CCR (Saadallah and Hulten, 1985). Theoretically, 64 different chromosomal combinations can be formed at the end of meiosis I and only two combinations are balanced. And empirically, the incidence of balanced embryos is very low in CCR carriers, ranging from 9.1 to 16.2% (Escudero et al., 2008; Lim et al., 2008b; Scriven et al., 2014). Since its introduction, PGD has contributed to the achievement of pregnancy and prevention of miscarriage in IVF-ET program of chromosome rearrangement carriers and it has been applied to IVF-ET program of CCR carriers.

Compared to PGD cycles of other chromosome rearrangement such as reciprocal translocation, Robertsonian translocation or inversion, the cancellation rate of embryo replacement is higher (25.0 ~ 64.7%) due to the absence of normal or balanced embryos in PGD cycle of CCR carriers (Table 3). The incidence of normal or balanced embryos is very low (4.9 ~ 5.6%) and therefore, the average number of transferred embryos is also small (1.7 ± 1.1 . per embryo replacement, unpublished data).

As mentioned above, meiotic segregation analysis of CCRs is very difficult due to the nature of CCR and its rarity. Although few studies have been conducted, meiotic segregation of three-way translocation, the most common CCR, is analyzed in several studies. The 3:3, 4:2 and 5:1 segregations are observed in embryos from three-way translocation carriers (34.1%, 20.7% and 2.2%, respectively). Among 3:3 segregations, the rates of alternate, adjacent 1 and adjacent 2 segregation are 16.4%, 52.5% and 31.1%, respectively. Cross-over between sister chromatids is observed in 7.3% of embryos. The 6:0 segregation is not observed and the meiotic segregation could not be determined in 43.0% of embryos (unpublished data). The incidence of embryos whose meiotic segregation mode cannot be determined is significantly higher ($P < 0.001$) in three-way translocation carriers (43.0%, unpublished data) than reciprocal translocation (16.8%) or Robertsonian translocation (14.4%) carriers (Ko et al., 2010, 2013). Various genomic, genetic and non-genetic factors can influence the meiotic segregation of translocation configurations (Jalbert et al., 1980). The number of chromosomes involved in a translocation is included in the factors. Also, the occurrence of double interstitial chiasma may affect the meiotic segregation of three-way translocation (Cifuentes et al., 1998). Therefore, in three-way translocation carriers, chaotic segregation may occur in at a higher incidence than two-way translocation carriers due to the involvement of three chromosomes and the occurrence of double interstitial chiasma although more extensive studies are needed to solve this problem.

Table 3. PGD outcomes of complex chromosome rearrangement carriers

References	Biopsy stage	% of normal or balanced embryos	% of clinical pregnancy	% of abnormal pregnancy*	% of ET cancel**	PGD techniques
Lim et al. (2008)	Cleavage stage	7.4 (4/54)	33.3	0	25.0	FISH
Escudero et al. (2008)	Cleavage stage	6.4 (9/140)	50.0		69.2	FISH
Scriven et al. (2014)	Cleavage stage	16.2 (6/37)	100		66.7	FISH
Ko et al. (Unpublished)	Cleavage stage	5.0 (22/444)	33.3	66.7	64.7	FISH

* Percent per embryos transfer.

** Embryo transfer was canceled because of the absence of normal/balanced embryos or insufficient quality of embryos for transfer.

Couples in whom one partner is a carrier of two different chromosome rearrangements has underwent PGD cycles. The incidence of embryos available to embryo replacement is low (4.9%, unpublished data) in those PGD cycles. Normal or balanced embryos for two different chromosome rearrangements are rare. Therefore, cancellation of embryo replacement due to the absence of normal or balanced embryos is high (about 77.8%, unpublished data). The two different chromosome rearrangements form two separate chromosomal configurations and undergo meiosis independently (Miller and Flatz, 1984; Zahed et al., 1998). In these PGD cycles, the meiotic segregation analysis is difficult as the number of analyzed embryos is very small and various chromosomes are involved in CCRs.

In some couples, both partners are carriers of chromosome rearrangements. Those couples can benefit from PGD. In PGD cycles of those couples, the incidence of normal or balanced is also very low (5.6%, unpublished data). The cancellation rate of embryo replacements is also very high. Similar to couples in whom one partner is a carrier of two different chromosome rearrangements, most of embryos that are normal or balanced in one chromosome rearrangement are unbalanced in the other chromosome rearrangement. The couples in whom both partners are carriers of chromosome rearrangements seem to have more reproductive risks than couples in whom one partner is a carrier of a chromosome rearrangement (Beyazyurek et al., 2010). Instead, the reproductive risks of those couples appear to be similar to those of couples in whom one partner is a carrier of two different chromosome rearrangements. The rate of normal or balanced embryos is similar between couples in whom both partners are carriers of chromosome rearrangements and couples in whom one partner is a carrier of two different chromosome rearrangements (5.6% vs. 4.9%, unpublished data). Strictly speaking, couples in whom both partners are carriers of chromosome rearrangements are not CCR carriers. However, the respective chromosome rearrangements of both partners seem to have a similar effect on pregnancy outcomes of PGD cycles to that of CCR carriers.

APPLICATION OF COMPREHENSIVE CHROMOSOME SCREENING (CCS) INTO PGD FOR BALANCED CHROMOSOME REARRANGEMENTS

With the development of PGD techniques, comprehensive chromosome screening using array CGH, SNP array or NGS is currently applied to PGD for balanced chromosome rearrangement carriers. In 2000s, FISH was the main technique of PGD for chromosome rearrangement. However, the techniques that can diagnose 24 chromosomes are currently applied to PGD for chromosome rearrangement carriers (Alfarawati et al., 2011; Fiorentino et al., 2011; Treff et al., 2011; Colls et al., 2012; van Uum et al., 2012; Huang et al., 2013; Tan et al., 2013). PGD for chromosome rearrangements is possible using these techniques and single blastomere biopsied from cleavage stage embryo, but recently 24-chromosome PGD combined with trophectoderm biopsy are expanding and gradually replacing the polar body or blastomere biopsy.

Compared to FISH-PGD using blastomere biopsied at day 3, array-based PGD combined with trophectoderm biopsy (day 5 or 6) results in higher clinical pregnancy rate and implantation rate (Tan et al. 2013). The number of embryos available for PGD is significantly higher in FISH-PGD than in array-based PGD. Only translocation-related chromosomes are diagnosed in FISH-PGD but 24 all chromosomes are diagnosed in array-based PGD. Therefore, the number of transferable embryos might decrease in array-based PGD. However, the average number of transferable embryos per embryo transfer is not significant different between FISH-PGD and array-based PGD (Tan et al., 2013). Instead, the rate of transferable embryos is higher in array-based PGD than in FISH-PGD. The higher rate of transferable embryos in array-based PGD might result from the small number of embryos available for PGD. And developmental potential of unbalanced embryos seems to be lower than that of normal or balanced embryos since the rate of transferable embryos is higher in array-based PGD than in FISH-PGD although the number of embryos available for PGD is larger in FISH-PGD than array-based PGD. In addition, miscarriage rate is higher in FISH-PGD than in array-based PGD although there is no significant difference (Tan et al., 2013). Abnormalities of chromosome rearrangement-unrelated chromosomes are observed in aborted tissues of FISH-PGD but not in aborted tissues of array-based PGD. Overall, array- or NGS-based PGD combined with trophectoderm biopsy can improve the clinical outcomes compared to FISH-PGD in PGD for chromosome rearrangement carriers. In the near future, array- or NGS-based PGD will be the major PGD technique for chromosome rearrangement carriers since its use is expanding.

CONCLUSION

Chromosome rearrangement carriers have achieved pregnancies by PGD after its introduction into human IVF-ET programs. In 2000s, FISH was widely used to PGD for chromosome rearrangement carriers and healthy babies were born. However, some of pregnancies achieved by PGD resulted in miscarriages that might be caused by abnormalities of chromosome rearrangement-unrelated chromosomes. PGD techniques for chromosome rearrangements have developed from diagnosis for only rearranged chromosomes to diagnosis for all chromosomes, from FISH to CCS using array CGH or NGS. With the development of

PGD techniques, miscarriages due to abnormalities of chromosome rearrangement-unrelated chromosomes will decrease and clinical outcomes of chromosome rearrangement carriers are expected to be improved. And although PGD techniques are developed, distinguishment between chromosomally normal embryos and balanced embryos is impossible with the PGD techniques we have today. Therefore, the techniques that can distinguish chromosomally normal embryos from balanced embryos have to be developed in the near future.

Lastly, though there are some exceptions, the possibility of obtaining normal or balanced embryos is higher in cycles that a large number of embryos are available for PGD than in cycles that a small number of embryos are available. Therefore, PGD might be performed by using as many embryos as possible. And also, the possibility of obtaining normal or balanced embryos is higher in cycles where a large number of embryos are obtained in one cycle compared to cycles where embryos are collected over several cycles. However, care should be taken to avoid excessive stimulation that may be harmful to patients and cause other side effects. With the development of PGD techniques, elaborate care for chromosome rearrangement carriers enable them to have healthy babies and will make possible the improvement of clinical outcomes of chromosome rearrangement carriers.

ABSTRACT

Aims: Attention deficit hyperactivity disorder (ADHD) is a multifactorial psychiatric and neurobehavioral disorder. The brain-derived neurotrophic factor gene (*BDNF*) has been proposed as a strong candidate for this pathology. The aim of this study was to determine a family-based association between three polymorphisms of the *BDNF* gene and the ADHD in a Tabascan-Mexican population.

Methods: We analyzed the rs6265, rs12273363 and rs11030119 polymorphism of the *BDNF* gene through a family-based association study. A total of 105 individuals grouped in family-trios (mother, father and ADHD patient) were studied. Allelic and haplotypic transmission were assessed through transmission disequilibrium test (TDT), using HaploView software.

Results: No statistically significant association was observed between the *BDNF* gene polymorphisms and the ADHD etiology in Tabascan-Mexican families: rs6265 ($\chi^2 = 1.33$; $p = 0.24$); rs12273363 ($\chi^2 = 1.33$; $p = 0.24$); rs11030119 ($\chi^2 = 0.66$; $p = 0.41$). Furthermore, no preference of transmission was observed for any of the haplotypes.

Conclusions: It was not possible to prove any association between the *BDNF* gene polymorphic variants and ADHD in a Mexican population. Future studies comprising larger samples are necessary to determine the potential role of the *BDNF* gene in ADHD.

Keywords: gene; Brain Derived Neurotrophic Factor (BDNF); Mexican population; Attention Deficit Hyperactivity Disorder (ADHD)

INTRODUCTION

Attention deficit hyperactivity disorder (ADHD) is one of the most common neuropsychiatric diseases in infancy and adolescence, with a higher frequency in men than women [1, 2]. Its world prevalence in the general population is high 3.4% (IC del 95%, 2.6-4.5) [3] and affects between 2 to 10% children in school age [4], of whom according to recent reports [5, 6], 80% continue showing ADHD symptoms through ought their lives. The frequency of its symptoms are catalogued as warning signs of this pathology as they highly affect the social, educational and working contexts of these individuals [7, 8]. There is genetic evidence that consistently supports the polygenic nature of ADHD with a heritability estimated between 75% and 91% [9, 10]. In this context, different alterations in neurotransmission pathways such as the dopaminergic [11], glutamatergic [12] and serotonergic [13] have been associated to the etiology of ADHD [14, 15]. Due to its contribution on the neural development, its role on the pharmacological action and its function on the dopaminergic pathway, literature proposes that the Brain Derived Neurotrophic Factor (*BDNF*) is a candidate gene that participates in the ADHD pathogenesis [16]. The *BDNF* gene is located on chromosome 11 at 11p14.1; at least 122 known polymorphisms have been studied for this gene (snpper.chip.org/bio/find-gene). One of the most studied polymorphisms is the Val66Met (G196A) [17], which has functional effects over the intracellular traffic and the pro-BDNF protein secretion when a Val66 is substituted by Met66 (18). However, the relation between the Val66Met of the *BDNF* and ADHD remains controversial because studies have shown positive and negative associations [19-31]. It should be noted that the majority of the studies about the *BDNF* as a candidate gene have been case-control studies [23, 29-33]; only a few

have evaluated the allele transmission in families [27, 29, 34], which we consider is the main reason for the inconclusive results obtained so far. Therefore, we decided to perform a family-based association study with the aim of comparing the allele and haplotypes transmission of the Val66Met *BDNF* polymorphism (rs6265) and the presence of ADHD. The rs12273363 and rs11030119 polymorphisms were also evaluated.

MATERIAL AND METHODS

Patients and Participants

The study comprised a total of 105 individuals of a Tabascan-Mexican population, grouped in 35 family-trios. Of the 35 probands, 32 were men and 3 were women (average age 7.7 years; age range 4-14 years).

Ethic Considerations

Patients were recruited from the outpatient clinic of the Children High Speciality Regional Hospital “Dr. Rodolfo Nieto Padrón” and the High Speciality Regional Hospital “Dr. Gustavo A. Rovirosa Pérez” in Villahermosa City of Tabasco State, Mexico. After receiving a verbal and written explanation of the study objectives, all participants voluntarily accepted to participate and their parents or legal guardians signed an informed consent to authorize the research. The study was approved by the research and bioethics committee of the Children High Speciality Regional Hospital “Dr. Rodolfo Nieto Padrón”.

Clinical Evaluation

ADHD diagnosis was engaged by a child psychiatrist using diagnostic criteria from the Diagnostic and Statistical Manual of Mental Disorders-Fifth Edition (DSM-V), [35]. All individuals were assessed based on their symptomatology and the information provided by the semi-structured interviews with parents and teachers; only patients that met the DSM-V criteria for ADHD were included in the study. Patients with another comorbid psychiatric condition, patients whose parents belong to different ethnicities and patients who refused the blood sample taking were excluded.

Genotyping Tests

The genomic DNA was obtained via the leukocytes extraction from peripheral blood using the Qiagen N. V. protocol of DNA extraction and purification (Puregene Blood Core Kit C, No. Cat. 15838).

Three *BDNF* gene polymorphisms were genotyped (rs6265 (Val66Met), rs12273363 and rs11030119) through the PCR amplifying technique using TacMan[®] 5' probe assays of Applied

Biosystems®. The primer sequences and their characteristics to amplify the three polymorphisms (rs6265, rs12273363 and rs11030119) are shown in Table 1. The fluorescence intensity was measured with the Applied Biosystems® Fast Real-Time PCR Systems 7900HT equipment and the genotypes were determined through allelic discrimination using the algorithm provided by the manufacturer along with the ABI PRISM® 7900HT SDS software version 2.4. A complete standardization was set following the standards of the Laboratory of Psychiatric and Neurodegenerative Diseases at the National Institute of Genomic Medicine (INMEGEN in Spanish) in Mexico City. The genotyping was performed blind to the clinical condition of the individuals.

Table 1. Main characteristics of the *BDNF* gene polymorphism SNPs rs6265, rs12273363 and rs11030119 (Data obtained from Applied Biosystems®)

SNP ID	Gene	Location	Sequence [VIC®/FAM™]	Polymorphism	[VIC®/FAM™]
rs6265	<i>BDNF</i> -AS	Chr.11:27679916	TCCTCATCCAACAGCTCTTCTATCA[G/A]GTGTTTCGAAAGTGTCAGCCAATGAT	G/A Transition and substitution	VIC: C FAM: T
rs11030119	<i>BDNF</i>	Chr.11:27728102	TTAAGTCACCACTCAGACTTTTCTC[A/G]TAGCAAAAGATCAGATCTCACAACC	A/G Transition and substitution	VIC: A FAM: G
rs12273363	<i>BDNF</i>	Chr.11:27744859	TGAGGCACAGCGATGCTGCAGAAGA[C/T]GGTGGATAGCTCTTAAGTTTCAGAC	C/T Transition and substitution	VIC: C FAM: T

Table 2. Allelic frequency and TDT analysis of the SNPs in the *BDNF* gene

Polymorphism	Alleles	HW	Lower frequency allele	Transmitted allele	T:NT	X ²	p value
Val66Met (rs6265)	G: A	1.0	0.12	C	8: 4	1.33	0.24
rs11030119	G: A	0.3	0.17	G	4: 2	0.66	0.41
rs12273363	T: C	1.0	0.12	T	8: 4	1.33	0.24

T – Transmitted allele; NT – Non-Transmitted allele; HW – Hardy – Weinberg equilibrium; p value – Probabililty value for the hypothesis tes (level of significance $p < 0.05$).

Statistical Analysis

The Hardy-Weinberg equilibrium was ascertained using the Pearson's Chi square (χ^2); all the genetic markers of parents and children genotyped were verified using the same test. The family-based association analysis was established using the Transmission Disequilibrium Test (TDT) [36], included in the HaploView Statistic Program version 4.2 (available on: www.broad.mit.edu/mpg/haploview) [37]; where the haplotypes were built for all the markers and the linkage disequilibrium values were examined with a Lewontin's D' minimum selected value of 0.08. The significance level was set as $p \leq 0.05$ with a 95% confidence interval (CI).

Table 3. Transmission haplotypes for the BDNF gene in ADHD families

Haplotypes block 1	Frequency	T:NT	χ^2	p value
CGT	0.700	17.0: 8.0	3.214	0.073
TGT	0.131	3.8: 8.5	1.826	0.176
CAC	0.112	3.0: 7.8	2.149	0.142
CAT	0.041	2.5: 2.7	0.009	0.922
CGC	0.011	0.3: 0.2	0.017	0.896

RESULTS

The TDT analysis results are shown in Table 2. No statistical significance was observed for the Val(G) allele transmission ($\chi^2 = 1.33$; $p = 0.24$). Similar results were seen for the other polymorphisms: rs11030119 ($\chi^2 = 0.66$; $p = 0.41$) and rs12273363 ($\chi^2 = 1.33$; $p = 0.24$). When the haplotypes analysis were performed, five common haplotypes were observed; however, no statistically significant differences were detected for any of the haplotype-blocks transmission (Table 3).

DISCUSSION

The objective of the present study was to evaluate the family-based association between the rs6265, rs12273363 and rs11030119 polymorphisms of the *BDNF* gene and attention deficit hyperactivity disorder in a Mexican population. Initially, the allelic transmission analysis was performed and the haplotypes analysis subsequently. In our population, no family-based association was observed, as none of the alleles (of the three polymorphisms studied) appeared to be over-transmitted from parents to probands. The result of no association based on families was also observed when haplotypes were analyzed. To our knowledge, this is the first study conducted in a Mexican population that analyses the genetic association between the *BDNF* gene and attention deficit hyperactivity disorder utilizing the transmission disequilibrium test (TDT).

Previous family-based association studies show that there is correlation between the *BDNF* gene and ADHD [23, 26, 30]; however, our results do not evidence a family transmission of the Val66Met (rs6265) polymorphism. Nevertheless, our results are similar to other studies [24, 25, 27-29, 31]; therefore, the rs6265 polymorphism role remains controversial. Furthermore, there are at least four meta-analysis that have evaluated the relation between the *BDNF* rs6265 polymorphism and ADHD and their evidence shows no association [16, 18, 19, 38], two of them specifically evaluated cases and controls [16, 18], while the other two included family-based studies as well as case-control studies [19, 38].

Some differences can explain the wide variation of the results. First, population ethnicities; so far, studies have been conducted on European and Asian populations (Caucasian and Mongoloid); as a consequence, there is high heterogeneity among the populations studied. As an example, the G/A alleles frequency in the Mexican population has been described as 79%

for the “G” allele and 20% for the “A” allele. In the present study, the prevalence observed for the “A” allele was lower than the previously reported (www.hapmap.org). When other populations have been analyzed, the frequency for the “A” allele can increased up to 61% as seen in Asian population; while the European population shows this allele as the least frequent in a range around 19%. Second, sample sizes of the studies that have used the TDT to analyze patients with ADHD have been very different; for instance, our analysis included 35 families, another study with significant values used a sample of 64 families [23], while reports with the largest samples have included 342 and 454 families [26, 29], respectively.

Finally, our “no association” observation was also seen in the haplotypes analysis. Likewise, Lee et. al., (2007) did not observe any correlation of the polymorphic variants rs2049046, rs6265 and rs11030104 in their sample (24); however, they found the A-G-G haplotype as the most frequent in relation with ADHD. On the other hand, Cho et. al., (2010) studied the rs6265 polymorphisms and other molecular markers (rs11030101 and rs16917204) and did not observe any possible risk related haplotype [31]. Overall, the results of the aforementioned studies (including ours), do not show a group of haplotypes involved in the ADHD pathogenesis.

Furthermore, there are just a few reports that have analyzed the rs12273363 and rs11030119 polymorphisms in other neuropsychiatric diseases [39-42]. To our knowledge, the present study is the first one to search for an association between the *BDNF* polymorphisms and ADHD (www.ncbi.nlm.nih.gov) in a Mexican population, though no association was found with any of the three SNPs proposed.

We acknowledge some limitations in our research. First, the small sample size made impossible to perform a sub-analysis by gender and also limits the statistical power of our analyses. Second, we did not evaluate other variables such as the severity of dominant-symptoms of the disorder. Therefore, the negative results found in our study, are not necessarily a refutation of the possible association between the *BDNF* gene and ADHD; the SNPs rs6265, rs12273363 and rs11030119 should still be important for future analyses, maybe for individual associations with ADHD symptoms.

There are also some strengths in our research: First, children with ADHD were evaluated and diagnosed by a child psychiatrist. Second, the association technique used in this research is more robust than the used in case-control studies; family-based association gives more information and one of the features of the transmission disequilibrium test is that it prevents possible spurious associations [43, 44]. Finally, only individuals from Tabasco State were included, which discards possible heterogeneity in the studied population.

CONCLUSION

Our findings suggest no association between the *BDNF* gene polymorphic variants and attention deficit hyperactivity disorder in a Mexican population. However, to determine the potential role of the *BDNF* gene and the development of ADHD we suggest that future studies comprise larger samples.

ABSTRACT

Petroleum can be characterized as an oily, flammable substance, less dense than water, with a distinctive scent and color ranging from black to dark brown. The petroleum industry includes some global processes that can be highlighted by the environmental risks they present. At offshore platforms, the danger of a spill is aggravated by the density of the oil, which floats and is carried quickly through sea currents. Thus, in addition to the marine fauna, coastal fauna and flora (e.g., mangroves and estuaries) can also be affected by a leakage. Petroleum is predominantly composed of hydrocarbons, these can be degraded by several species of bacteria, which are of great interest for the bioremediation of contaminated environments. Among these species we can mention *Pseudomonas*, *Sphingomonas*, *Mycobacterium*, *Microbacterium* and *Gordonia*. The success of a bioremediation process depends on numerous factors such as microbial biomass, population diversity, enzymatic activity, pH, temperature, and carbon source. Moreover, the strains have their genetic potential for bioremediation investigated through methods of analysis concerning genes related to the degradation of aliphatic and aromatic hydrocarbons mostly by oxygenases, such as the polycyclic aromatic hydrocarbon ring-hydroxylating dioxygenases (PAH-RHD α), and *alkB* (for n-alkane degradation) genes. The study of autochthonous microbial communities is of crucial importance for the understanding of the genetic and biotechnological potential of bioremediation in environments close to the areas of extraction and susceptible of contamination; it is also of great interest for industry and biotechnological development. This chapter covers the main aspects of petroleum, regarding its exploitation aspects, the process of geological formation, and environmental impacts. It will include topics in microbiology and genetics; for instance, metabolic pathways of hydrocarbon biodegradation, biofilm dynamics

associated to the oil industry, metagenomics of communities in marine environments, corrosion influenced by microorganisms (CIM), microbial control methods related to the petroleum industry, and bioremediation will be discussed.

1. INTRODUCTION

The importance of oil to the daily lives of the population and global industry is huge, but also carries with it a great risk to the environment. Risks are associated with accidental spills and leaks during the exploration, production, refinement and especially transportation and storage of this product and its derivatives. Large environmental disasters, such as the Exxon Valdez ship and the Deepwater Horizon, wreck the local ecosystem and therefore draw attention to community studies in contaminated areas or possible oil contamination.

Petroleum consists predominantly of hydrocarbons, which can account for 97% of its composition and, to a lesser extent, organic, sulfur, nitrogenous, oxygenated and organometallic derivatives. Due to the predominance of hydrocarbons in petroleum, these are the most used compounds as indicators of this type of pollution, and can be divided into four classes: saturated, aromatic, asphaltenes (phenols, fatty acids, ketones, esters and porphyrins), and the resins (pyridines, quinolines, carbazols, sulfoxides and amides).

The hydrocarbons released into the environment are one of the worst forms of pollution that exists for water, soil, flora and fauna. This is because they are generally very hydrophobic compounds capable of penetrating cell membranes causing mutations, and in humans can cause cancer. These hydrocarbons also accumulate in the trophic chain, making their concentration even greater for humans. Microbiological and genetic aspects will be addressed in the following topics in order to provide a background of the importance of microbes to the petroleum industry and to the environment.

1.1. Formation of Petroleum in Relation to Geological Processes

Petroleum (from Greek: *petra*: “rock” + *oleum*: “oil”) is a mixture of oily substances, flammable, generally less dense than water, with a distinctive scent and coloring that can range from colorless or light brown to black, through to green and brown (brown), naturally occurring, found in geological formations beneath the Earth's surface. A complex mixture of hydrocarbons and varying amounts of non-hydrocarbons, among these molecules we can point out from n-alkanes to aromatic compounds containing sulfur (sulfides) and nitrogen (pyridines and indoles). In addition, the petroleum still has some organometallic constituents such as vanadium and nickel [1]. When it occurs in the liquid state in subsurface or surface reservoirs, it is termed oil (or crude oil, to differentiate from the refined oil. It is known as condensate the hydrocarbon mixture which is in the gaseous state in subsurface and becomes liquid at the surface. The term natural gas refers to the fraction of oil that occurs in the gaseous state or in solution in the oil in subsurface reservoirs [2].

1.1.1. The Origins of Oil

The first theories that tried to explain the occurrence of the petroleum postulated an inorganic origin, from the reactions that would occur in the mantle. Even today there are authors

who advocate an inorganic origin for petroleum, either from the polymerization of methane from the mantle and migrated through faults, or from reactions equivalent to those employed in the Fischer-Tropsch synthesis, and which would find favorable conditions for its occurrence in the subduction zones [3]. Several facts, however, favor an organic origin for most of the hydrocarbons found near the Earth's surface, in particular for those with two or more carbon atoms. Oil is formed in the earth's crust as a result of the partial anaerobic decomposition of organic matter (animal, plant, and plankton) deposited in the bottom of seas and lakes. The product generated from this partial anaerobic decomposition is subsequently transformed under high pressure and at temperatures up to 150°C. Transformation reactions occur at catalytic sites present in the adjacencies of rock surfaces in the presence of water, sulfuric acid, sulfur, and other inorganic compounds [4].

1.1.2. Determinant Factors of the Petroleum's Occurrence in Sedimentary Basins

The most accepted hypothesis considers that, with the increase of the temperature, the molecules of kerogen found in the Earth's underground layers would begin to be broken, generating liquid and gaseous organic compounds, in a process called catagenesis. In order to have an accumulation of oil, it would be necessary to migrate the oil and/or gas through the layers of adjacent and porous rocks, until a sealing rock and a structure That accumulates oil and/or gas in a porous rock called reservoir rock. It is accepted by most geologists and geochemists that it is formed from organic substances from the earth's surface (organic debris), but this is not the only theory about its formation [4].

The formation of an accumulation of oil in a sedimentary basin requires the association of a number of factors:

- The existence of rocks rich in organic matter, called generating rocks;
- The generating rocks must be submitted to the appropriate conditions (time and temperature) for the generation of the oil;
- The existence of rocks with porosity and permeability required for the accumulation and production of oil, called reservoir rocks;
- The presence of favorable conditions for the migration of oil from the generating rock to the reservoir rock;
- The existence of an impermeable rock that holds the oil, called a sealant rock or cape;
- A geometric arrangement of the reservoir and sealant rocks that favors the accumulation of a significant volume of oil.

A commercial accumulation of oil is the result of an adequate association of these factors in time and space. The absence of only one of these factors makes the formation of an oil deposit impossible.

1.1.2.1. Generating Rock

A generating rock must have organic matter in adequate quality and quantity and submitted to the stage of thermal evolution necessary for degradation of the kerogen. It is generally accepted that a generating rock should contain a minimum of 0.5 to 1.0% of total organic carbon (TOC) content. The volumetric aspects of the generating rock (thickness and lateral extension)

should also not be ignored, since a rock with adequate quantity and quality of organic matter can be, for example, too thin to generate commercial quantities of petroleum [5, 6]. The term organic matter refers to the material present in sedimentary rocks, which is derived from the organic part of living things. The quantity and quality of the organic matter present in the sedimentary rocks reflects a series of factors, such as the nature of the biomass, the balance between production and preservation of organic matter, and the physical and chemical conditions of the depositional paleoenvironment [5].

1.1.2.2. Reservoir Rocks

The crude oil formed and the other substances do not remain in the rock on which they are generated, the matrix rock, but they move to the sedimentary basins or reservoir rocks where they accumulate occupying the pores. Layers or porous sheets of sand, sandstone or limestone forms the reservoir rocks. It is the permeability of reservoir rocks that will allow the production of oil. Because it has a lower density than the rocks that make up the subsoil, oil tends to migrate to the surface. When petroleum encounters an impermeable structure on the way to the surface that confines it and prevents its migration, slow formation (a few thousand years) of an oil reservoir will occur [6–8]. In this place are the natural gas, in the highest part, and oil and water in the lowest [7].

1.1.2.3. Conversion of Kerogen into Oil

Three phases are recognized in the evolution of organic matter as a function of temperature increase: diagenesis, catagenesis and metagenesis [8, 9]. The diagenesis occurs after the deposition of the organic matter, under small depths and low temperatures, resulting in the transformation of the original organic matter into kerogen. During diagenesis, methane is the only hydrocarbon generated in significant amounts. During catagenesis, the kerogen is subjected to even higher temperatures (in the range of 50 to 150°C), which results in the successive formation of oil, condensate, and moist gas [9]. The end of the catagenesis is reached at the stage where the kerogen has completed the loss of its aliphatic chains. In metagenesis, achieved under very high temperature (above 150–200°C), the organic matter is represented basically by dry gas (methane) and a carbonaceous residue.

In order to characterize the evolution of the kerogen transformation process in petroleum, two parameters are used: the genetic potential (or potential), defined as the amount of oil (oil and gas) that a kerogen is able to generate, and the rate of transformation, defined as the ratio between the amount of oil generated and the original genetic potential [7, 9]. The original generator potential refers to the kerogen that has not yet been subjected to the catagenesis, that is, whose transformation rate is zero. From the beginning of the catagenesis, the conversion of the kerogen into petroleum causes a progressive increase of the transformation rate associated with the reduction of the generating potential, which is called residual [8].

1.1.3. Petroleum Migration and Accumulation: Primary and Secondary Migration

The process of expulsion of oil from the generating rocks, an essential factor for the formation of commercial accumulations, is called primary migration. Various theories and hypotheses have been proposed in order to explain the mechanisms and factors controlling the expulsion of oil from its generating rock [6, 8, 9]. During primary migration, gas, and oil travel together as a single liquid phase due to the high pressures in the generating rock as these pressures usually become higher than the bubble point pressure. After some time, expulsion

from the matrix rock may occur in pulses due to the closure of pores and fractures from the first expulsion. Gradually, petroleum creates enough pressure to reopen these fractures causing a second expulsion, and the pulses continue to happen as long as the petroleum can rebuild enough pressure to reopen its path out of the rock. After migration, the pressure decreases and the pores close. Lastly, petroleum migrates out of the generating rock and, pressures decay [8, 9].

Among the suggested mechanisms, the migration of oil in solution in water and by molecular diffusion is highlighted. With the advances within this field, it was shown that these mechanisms, although working, do not have the necessary efficiency for the expulsion of significant volumes of petroleum.

The dislocation of the oil between the generating rock and the trap is called secondary migration. It consists of a continuous flow, driven by the fluid potential gradient. This potential can be subdivided into three components: I. pressure unbalance caused by compaction, II. buoyancy, consisting of the vertical force resulting from the difference in density between oil and forming water; And, III the capillary pressure resulting from the interfacial tension between the oil and water phases and the rocks [9]. Finally, it is crucial to mention necessities for favorable petroleum accumulations as these accumulations will supply the world with its needs of petroleum.

1.2. Petroleum Composition

Oil contains hundreds of different compounds. In elementary terms, petroleum consists essentially of carbon (80 to 90% by weight), hydrogen (10 to 15%), sulfur (up to 5%), oxygen (up to 4%), nitrogen and other elements (e.g., nickel, vanadium, etc.). The composition of petroleum is generally described in terms of the proportion of saturated hydrocarbons, aromatic hydrocarbons, and non-hydrocarbons [2].

Saturated hydrocarbons, C and H compounds attached by single bonds, include normal alkanes (normal paraffins or n-alkanes), isoalkanes (isoparaffins or branched alkanes) and cycloalkanes (cyclic alkanes or naphthenes). N-alkanes of less than 5 carbon atoms (methane, ethane, propane, and butane) occur as gas at normal pressure and temperature, while those with 5 to 15 carbon atoms are liquid and those with more than 15 carbon atoms vary from viscous liquids to solids. Most of the normal alkanes present in petroleum have up to 40 carbon atoms. Isoalkanes are present primarily with compounds of up to 10 carbon atoms, although occurring up to 25 atoms. Cycloalkanes may have up to 6 carbon rings, each having 5 or 6 carbon atoms, and cycloalkanes occur mainly in the liquid state [2].

Aromatic hydrocarbons are compounds that have the aromatic ring (benzene) and always occur in the liquid state. They may contain more than one aromatic ring, such as naphthalenes (2 rings) and phenanthrene (3 rings). Toluene, with only one benzene nucleus, is the most common aromatic compound in petroleum, followed by xylene and benzene. Finally, non-hydrocarbons are compounds that contain other elements, other than carbon and hydrogen, called heteroatoms. As the elements nitrogen, sulfur and oxygen are the most common heteroatoms, these compounds are generally known as NSO. It is also common the occurrence of metals (especially nickel and vanadium) associated with organic matter in compounds called organometallic. Resins and asphaltenes are high molecular weight NSO compounds, poorly soluble in organic solvents. Its basic structure consists of 'layers' of condensed polyaromatic

compounds, stacked in the form of aggregates. The proportion of resins and mainly asphaltenes in petroleum is directly proportional to their viscosity [10].

Petroleum hydrocarbons comprise n-alkanes, isoalkanes, cycloalkanes, and aromatics. Among these, the predominant are the n-alkanes and the alkanes with branched chains. These compounds contain amounts of carbon varying from 1 to 78 atoms in some types of oil [11]. The most important branched group is formed by isoprenoids containing 13 carbon atoms, pristane and phytane having 19 and 20 carbon atoms, respectively [12]. The cyclo alkanes, also called the paraffin or naphthenes cycle, are also important constituents, but found in lesser amounts in petroleum. Aromatic naphthenes have saturated and aromatic cyclic structures at the same time. Refined products like gasoline, diesel, lubricating oils, kerosene, fuel oil contain the same compounds as petroleum, but with a range of different boiling points. In addition, in a refining process, such as cracking, there are olefins (alkenes and cycloalkenes), which exist in high concentration in gasoline [13].

There are basically two types of oil classifications. Those proposed by engineers are based on the composition and physical-chemical properties of the oil (density, viscosity, etc.) and are geared to the production and refining areas. On the other hand, the classifications proposed by geologists emphasize the composition, being directed to the origin and evolution of the oil. Among the classifications of geological character, one of the most used is the one proposed by Tissot & Welte (1978) that divides the oils into six types: paraffinic, paraffinic-naphthenic, naphthenic, aromatic intermediate, aromatic-asphaltic and aromatic-naphthenic. The composition of each type reflects the origin, the degree of thermal evolution and the alteration processes to which the oil was subjected.

Another form of occurrence of hydrocarbons are gas hydrates, which consist of ice crystals with gas molecules (ethane, propane and, mainly, methane). Gas hydrates occur under very specific conditions of pressure and temperature, being more common in shallow deposits in the polar regions or in deep waters at various points on the planet. It is commonly refined into various types of fuels. Components of petroleum are separated using a technique called fractional distillation i.e., separation of a liquid mixture into fractions differing in boiling point by means of distillation, typically using a fractionating column [14].

1.3. General Concepts Concerning Oil Industry: Exploitation, Recovery and Refining Process

The petroleum results from anaerobic organic matter degradation that takes around thousands of years to finally form an oil quarry [15]. Although this long-term formation process, petroleum quarries last no longer than 32 years since its discovery until oil well abandonment. The well abandonment occurs in the last phase of a reservoir operational life caused by low costs-benefits in oil/gas production. A premature well closing can also happen and its commonly associated with microbiological presence/activity in the oil fields which leads to adverse risks to environmental and human security [16, 17].

The operational life of an oil well begins with the discovery step, which generally involves prospecting with seismic methods. The prospecting process can suggest the most suitable site for a well drilling, signaling a potential oil quarry location. The seismic reflection method is one of the main tools for oil prospection used by petroleum industries. This method is based on seismic waves emitted by a generator source (any source of mechanical vibrations) that can be

detected by a receptor. The mechanical vibrations can be generated by explosives, air guns (offshore prospecting), weight-dropping (onshore prospecting) among others. The waves that were reflected from the interface between different rocks, with distinct petrophysics composition, are captured by the receptor (recording equipment). The seismic interpretation is based in the relationship between rocks density and seismic waves rate. Since the rocks present different densities, the waves will pass through dense rocks faster when compared with porous rocks. The different reflection coefficient from the surface rocks can provide geologists an advice of a sedimentary basin with a petroleum reservoir rock [18].

The oil well drilling is the most expensive step in the petroleum exploitation process with great economic risks. The well drilling is performed in a 3-8-stage process using a wheel probe. The numbers of stages involved are related to rocks characteristics and well deep. During a stage, the wheel probe drills the rocks surface using drill rotation and the own weight of the drilling column. The rocks fragments are removed by the drilling fluid or mud, a complex mixture of solids, liquid and gas, which is pump injected inside the drilling column and returns to the surface using the annulus of the well (the space between well walls and the drilling column). After that, the drill column is replaced by a steel coating column and the annulus space is concrete fulfilled. Thereafter, a new stage begins with the introduction of a thinner drilling column in the well. The oil well drilling also contents some additional steps as coring, logging and completion. The coring process aims to obtain a real sample from the subsurface rock (core sample) as a representative sample of the formation. This step can predict well productivity. In the following, logging process characterizes an oil well as cost-effective or not. This process consists on the assessment of rock properties using a logging probe that can indicate if there are oil/gas in quantity to warrant the completion process. This last one is an operational set that aims to prepare the well to start oil/gas production with or without fluids injection in a safe and cost-effective manner [19, 20].

It is also important to highlight that during drilling process potential and dangerous accidents can happens such as oil productive well explosion after a blowout process. The blowout is characterized by the uncontrolled flow of the formation fluid in the surface way and it starts as a kick. The kick happens when the well pressure (fluid formation) is higher than drilling mud pressure. Consequently, the formation fluids came from the drilling column pushing the drilling mud to the surface and can result in a fire accident [19].

In the following step, the oil recovery consists basically in three stages. The first stage is called primary recovery or production. In this stage, hydrocarbons are displaced from the reservoir into the wellbore up the surface using natural reservoir energy, such as gasdrive, waterdrive or gravity drainage. In the primary production, the reservoir natural pressure is significantly higher than the bottom hole pressure, which can drive the oil toward the well and up to the surface. Although, as long as the reservoir pressure declines, so does the oil well production. This natural pressure could be increased using artificial lift system such as rod pumps (horsehead pump) among others. The primary recovery stage ends when the natural pressure is too low that oil production is not economical or when water/gas production is too high in the production stream. The primary production provides only a small percentage (around 15%) of the initial hydrocarbons present in the reservoir [21, 22].

The next stage in oil recovery is called secondary recovery or production. This secondary stage aims to maintain reservoir pressure by the injection of an external fluid into the reservoir to displace the oil towards the wellbore. The secondary recovery usually employs water or gas to enhance reservoir pressure. These technics are named as waterflooding and gas injection,

respectively. In this stage, the injection fluid is injected into the reservoir by the injection wells and the oil is collected in the end of this process in the production well. The injection and production wells have fluid communication under the rock surface. In this process, the gas is usually injected into the gas cap and water is injected into the production zone to displace hydrocarbons from the well. The secondary recovery finishes when oil production is not economical anymore and the injected fluid is produced in a considered amount. The secondary production along with primary production can recover up to 60% of the initial oil in place [18, 22].

The third and last stage in oil recovery was traditionally named as tertiary recovery. The tertiary recovery is characterized as a set of methods used to enhance oil recovery that originally followed primary and second production process. Nowadays, these enhanced methods can be applied at any time during the hydrocarbons production process and the term tertiary recovery became outdated. Therefore, the term enhanced oil recovery (EOR), also known as improved oil recovered, is more commonly used to specify the use of sophisticated technics that aims not only to maintain reservoir pressure, but also to promote hydrocarbons displacement with fluid flow inside the oil well. For this purpose, EOR technics alter oil original properties and they are based in three operational major types: i. the chemical flooding (alkaline or micellar-polymer approaches); miscible displacement (carbon dioxide and hydrocarbon injection); and thermal recovery (steamflood or in situ combustion). Some reservoirs conditions (temperature, pressure, depth, permeability, rock porosity among others), residual oil and water saturations inside the reservoir, and petroleum properties such as oil API gravity and viscosity are main factors that can influence the optimal application of each type of EOR [18, 23, 24].

The EOR technics can also include the use of microorganisms to improve oil recovery in an oil well. In this case, this technic is known as microbial enhanced oil recovery (MEOR). The MEOR technics involve basically target microorganisms and/or their metabolic products (gas, acid, solvents, polymers, biosurfactants and bioemulsifiers) injection into the reservoir, or nutrient injection to promote this target microbiota development inside the well. A variety of mechanisms can be considered when MEOR is applied to enhance oil recovery. These mechanisms used by microorganisms to improve oil production are summarized in Table X. Despite of MEOR mechanism involved, these mechanisms are based on oil viscosity decreasing, enhance of fluid mobility and oil displacement from the reservoirs rocks, and enhance of oil solubility or miscibility in water. The MEOR consists of an interesting green and economical alternative for EOR technics that includes complex technics with high energy uptake (thermal recovery) and financial costs (chemicals improvement) that can lead to environmental impacts [25, 26].

After the oil extraction, the fluids go to a tank for oil/water separation and then, the oil is transported from onshore and offshore platforms basically by pipelines and oils tankers to petroleum refiners. The crude oil is a complex mixture of hydrocarbons which requires refining to be converted in petroleum derivatives such as liquified petroleum gas (LPG, propane and butane) gasoline, diesel, kerosene (jet fuel), naphtha, heating oil, base oil (lubricants) and asphalts (bitumen). The oil by-products are generated from three major refining processes: separation, conversion and treating [27–29].

Table 1. The microbial enhanced oil recovery (MEOR) main mechanisms used by microorganisms to improve oil production

Bioproduct	Example	Activity
Gas	Carbon dioxide and methane	Preferential solubility in oil
Acids	Acetic, butyric and lactic acids	Enhance porosity of reservoirs rocks
Solvents	Ethanol, butanol and acetones	Affect oil/rock interactions
Biosurfactants	Glycolipids and lipopeptides	Decreases surface tension between oil/rock and oil/water
Biopolymers	Polysaccharides and proteins	Controls oil physical mobility/Bioemulsifiers
Microbial Biomass	Anaerobic and aerobic microorganisms	Hydrocarbons degradation/Biofilm formation

The separation step consists in hydrocarbons segregation in a distillation column. Inside the column, the oil is heated with high temperatures (around 350-400°C) leading hydrocarbons to vaporize according to their molecular weight. During this process, small chains hydrocarbons vaporize first while heaviest molecules remain at the bottom of the distillation column without vaporizing. In the following, the molecules condense into liquids according to the temperature inside the column and petroleum fractions or cuts are collected. In the end of the separation process, the distillation column presents highly viscous hydrocarbons like asphalt (bitumen) and gases at the column bottom and top, respectively. The conversion step aims to “crack” heavy molecules, remaining from the previous step, in to lighters products to reach the market demand. This step also applies high temperatures together with a catalyst to speed up heavy products conversion into gas, gasoline and diesel. The final refining step is known as treating and it consists on remove or reduces significantly corrosive and potential polluting molecules from refined products, especially the sulfur. As an example, the diesel desulfurization or sulfur removal occurs at high temperatures and pression with hydrogen addition. The hydrogen combined with the sulfur forms hydrogen sulfide (H₂S) which is treated and removed. Another refine products as kerosene, butane and propane are treated with caustic soda (sodium hydroxide) to remove thiols (mercaptans) in a sweetening process. The automotive fuels steel needs a treatment to produce high-octane products. This treatment, known as catalytic reforming, involves chemical reactions at high temperature and pressure using platinum as a catalyst. The catalytic reforming promotes naphthenic hydrocarbons conversion into higher-octane rate hydrocarbons, as the aromatics ones. Another process that increases octane rating is the alkylation, one of the main chemical reactions used in the petrochemical industry [27–29].

1.4. Petroleum and the Environment: Pollution and Environmental Impacts

Oil is a naturally occurring substance, its presence in the environment is not necessarily the result of human intervention, such as accidents and extraction, refining and combustion. Phenomena such as exudates are examples of areas where oil affects the environment without the man's involvement. Regardless of the source, the effects of oil are similar when released into the environment. In the last century, there has been a large increase in global pollution. Industrial development, population growth, urbanization, and unconcern with the ecological consequences of the dumping of chemical compounds in nature have contributed to the current level of pollution and, consequently, environmental issues. A large number of industries, especially the oil and gas industries, have contributed significantly to the environmental pollution reaching the present dangerous proportions. In addition, there has been a drastic increase in the diversity of industrially produced organic compounds that have been inconsistently discarded in the environment. Due to this fact, there are now innumerable chemical contaminants that are toxic to biological systems from both natural (biogenic and geochemical) sources and anthropogenic sources [30].

1.4.1. Acidification of the Oceans

Ocean acidification is the name given to the chemical imbalance by decrease in pH in the oceans caused by the increase in atmospheric carbon dioxide (CO₂), meaning an increase in acidity. Since the beginning of the 19th century, when carbon emissions began to rise rapidly, the pH of the ocean surface decreased by about 0.1 on the logarithmic pH scale. Although this difference seems small in reason of the type of scale used, it represents an increase of about 10% in the concentration of H⁺ hydrogen ions, the direct ones responsible for acidification. The rise of CO₂ levels in the atmosphere has its origins in human activities, especially in the burning of fossil fuels (oil, natural gas, coal and, others), but also in deforestation, in some industrial processes and in other smaller sources. Ocean acidification inhibits all marine life - has a greater impact on smaller organisms and then affects larger organisms [31].

Contamination may result from the deliberate dumping and discarding of hazardous materials, from accidental spills, and from the migration of hazardous substances from spills occurring elsewhere. Soil pollution can lead to the contamination of underground aquifers as the contaminant begins to percolate over time through rainwater paths in the soil leading to the water table. Contamination of groundwater can affect at least two million people in the world who depend directly on aquifers for drinking water [30].

1.4.2. Oil Spills

Soil and water contamination represents a serious problem to human health and to the affected area's ecology [30]. Since the most toxic compounds are the most soluble and volatile components, the chemical impact is greatest in the first few days after the spill in most cases. The chemical effect or impact is associated with the toxicity of the compounds present in the oil. Saturated hydrocarbons have anesthetic and necrotic effects on living beings. Alkanes, popularly known as paraffins, and which account for much of the crude oil, may also cause anesthetic and narcotizing effects [32]. Low molecular weight hydrocarbons (C₁₂ to C₂₄) have an intense acute toxic effect, mainly due to their high solubility and consequent bioavailability [33].

The contact of organisms with toxic fractions of the oil can lead to death by intoxication, especially associated with the fractions of aromatic compounds. Among the most toxic components are benzene, toluene, and xylene. Aromatic hydrocarbons having multiple benzene rings are known as Polycyclic Aromatic Hydrocarbons (PAHs). It is known that these compounds are more resistant to the microbiological biodegradation and quite persistent in the environment, being strongly adsorbed in the sediments. Some common examples of PAHs and derivatives in petroleum are naphthalene, anthracene, phenanthrene and benzopyrene and their various isomers. PAHs are especially toxic, potentially carcinogenic to humans, and the tendency of these compounds to be incorporated into fatty tissues and to cause damage to organs such as the liver and kidneys of humans has been proven [34]. Its mutagenic activity is strongly related to its molecular structure. The molecular form of PAH isomers, therefore, is directly related to biological activity and, consequently, to its toxicity [35].

The environmental impacts caused by the petroleum industry come from the exploration, transportation, refining and use of its products [32–35]. Crude oil and refined fuel spills from tanker ship accidents have damaged natural ecosystems in Alaska, the Gulf of Mexico, the Galapagos Islands, France, and many other places. These activities are involved in 90% of the accidents resulting from the exploration and use of oil, and only the remaining 10% are attributed to oil spill catastrophes in the high seas resulting in contamination of coastal regions [34,35]. As an example of an environmental catastrophe, we can mention the case of the Exxon Valdez oil tanker, which in 1989 spilled about 50,000 m³ to 150,000 m³ of oil in the Alaska Sea [36]. As a result of the spill, thousands of animals died in the following months, among them: sea birds, otters, eagles, killer whales, and billions of salmon eggs. In France, March 1978, the oil tanker Amoco Cadiz ran aground on Portsall Rocks, 5 km (3.1 mi) from the coast of Brittany, and ultimately split in three and sank, the consequences from this accident resulted in one of the largest oil spills of its kind in history to the present date.

The consequences of industrial pollution for human health and the environment have led to public demands for the cleaning and restoration of the environment, as well as the creation of governmental regulations and legal actions. The result has been the search for remediation technologies that can be actively applied to cleaning soil and aquifers [31].

1.5. The Microbiome of Oil Reservoirs

Oil reservoirs are characterized by high pressure, high osmosis (salinity or hydrophobicity) and high temperature, and these factors were considered impossible for a long time, being oil considered sterile [37]. Besides the harsh conditions, oil reservoirs contain inorganic ions such as iron, sulfate, nitrate and organic compounds from petroleum (see section 1) and derived from microbial activity [38].

The first microbiological study describing bacteria in oil-reservoirs was published by Bastin in 1926, and he raised a question: the bacteria found in oil-producing wells could be considered indigenous or not? [39]. Indeed, is very difficult to access the indigenous community without to contaminate with exogenous microbes, but it is probably dominated by anaerobic ones, once the deep subsurface has no oxygen [40].

Technical advances of the molecular biology as well as microbiology shone light on the microbial diversity of extreme environments and it made possible to detect and sometimes isolate microbes from oil-producing reservoirs that were able to grow at those challenging

conditions [1, 37, 40–43]. Several studies have been done to assess not only the microbial diversity of oil reservoirs, but (i) how these communities react to physical-chemical changes, (ii) hydrocarbon degradation mechanisms, (iii) microbial steel corrosion in oil-producing wells [1, 40, 43–45].

Many factors can affect microbial composition, such as temperature and pH and biological interactions, kind of reservoir (onshore, offshore, freshwater, seawater, surface soil) [40]. Temperatures above 82°C are considered the limit for growth on oil, because biological molecules denature at this temperature. However, some hyperthermophilic exogenous microbes growing at 103°C were isolated from oil reservoir contaminated with seawater [40]. The pH of an oil reservoir ranges from 3 to 7 and pressure can be up to 500 atm. These conditions can limit the microbiological activity.

The absence of oxygen at deep subsurface and availability of sulphate, carbonate, CO₂ and H₂, led anaerobes to realize sulphate reduction, methanogenesis, acetogenesis and fermentation process. In fact, oil reservoir microbiome is dominated by heterotrophics, thermophiles and lithotrophics bacteria, and methanogenic archaea.

Sulfate reducing microbes oxidize organic compounds reducing sulfate (SO₄²⁻) into sulfide (H₂S). The main taxa found in oil reservoir are *Desulfovibrio*, *Desulfobacter*, *Desulfotomaculum*, *Desulfobacterium*, *Desulfomicrobium*, *Thermodesulfobacterium*, *Thermodesulforhabdus* bacterial genera and *Archaeoglobus* archaeal genus. Mesophilic sulfate reducing bacteria (SRB) have optimum growth temperature around 37°C, while thermophilic SRBs grow better at 60°C, but tolerates up to 80°C. Both mesophilic and thermophilic can oxidize a wide range of substrate such as acetate, lactate, pyruvate or even C17 organic compounds [40].

Methanogenic archaea are the only microorganisms able to produce methane from simple carbon compounds (C₁-C₄). In oil reservoirs, methanogens reduce CO₂ to CH₄ using H₂ as electron donor, the so-called hydrogenotrophic pathway, but sometimes acetoclastic (using acetate instead of CO₂) route can be used [46]. Methanogens can tolerate salinity of up to 30%, and temperature up to 80°C [40].

Fermentative bacteria can also be found in oil-producing wells, among them many bacterial genera able to use carbohydrate to produce a wide range of acids, alcohol and gases under anaerobic conditions. Many halotolerant mesophilic and thermophilic fermentative bacteria have been reported, such as *Haloanaerobium*, *Spirocheta*, *Geotoga*, *Anaerobaculum* are examples.

Mesophilic and thermophilic iron reducing bacteria can be detected in oil field fluids due to the presence of metals in the apparatus of oil extraction [47]. *Shewanella putrefaciens* (formerly *Alteromonas putrefaciens*) is a bacterium that can reduce sulphur, sulphite and thiosulphate into sulphide using H₂ and Fe [47].

1.6. Petroleum Degrading Genes and Metabolic Pathways

As seen on the previous topic, oil reservoirs are characterized by harsh conditions for life and the microbial activity is low. However, after petroleum is extracted from wells, it is contaminated with exogenous microbes (mainly from seawater or marine sediments) whose begins to degrade hydrocarbons. Microbial degradation of petroleum hydrocarbons depends on

the nature of hydrocarbon and physical-chemical conditions such as availability of oxygen, nutrients, temperature, salinity and others [48].

Biochemical mechanisms for hydrocarbon degradation is well described on the literature [48–54]. Under aerobic conditions, oxygen is introduced on hydrocarbons by mono- and dioxygenases and is faster than the anaerobic degradation. Mono and dioxygenases add oxygen atoms to hydrocarbons producing fatty acids that go to β -oxidation and generate acetyl-CoA for the tricarboxylic acid (TCA) cycle. At this process, NADH and FADH are the electron donors [52]. After TCA cycle, carbon intermediary compounds are assimilated for biosynthesis and cell growth [48].

Anaerobic degradation needs to insert fumarate into hydrocarbon molecules and uses inorganic ions such as sulfate, nitrate and iron as terminal electron acceptors [52], resulting in fatty acids that go to β -oxidation producing acetyl-CoA or benzoyl-CoA [48]. Some aromatic compounds, such as benzoate, can be degrade by adding coenzyme A producing acetate and propionyl-CoA (addressed to TCA cycle) [48].

Methane is a hydrocarbon that can be degraded aero and anaerobically. Under aerobic conditions is oxidized to CO_2 by methylophilic bacteria (able to use methane and other C1 compounds). Methanotrophic bacteria use enzymes called methane monooxygenases to oxidize methane, which is the sole source of carbon and energy of this bacterial group. In marine sediments, methane can be oxidized without oxygen by a consortium of sulfate-reducing bacteria (SRBs) and archaea from ANME (anaerobic methanotroph) group. ANME archaea oxidize methane by using it as electron donor, which go to SRBs to reduce SO_4^{2-} to H_2S [55].

As discussed on the beginning of the chapter, petroleum is a heterogeneous compound, which requires several classes of genes and metabolic pathways to be degraded. Environmental conditions such as pH, oxygen availability, nutrient (mainly N and P), temperature and salinity can affect petroleum degradability and enzyme activities [56, 57]. The main microbial enzymes responsible for petroleum degradation are summarized on the table below [48, 58].

Table 2. Main microbial enzymes classes related to petroleum compounds degradation

Enzyme class	Substrate range	Hydrocarbon	Example of bacterial genus
Soluble methane Monooxygenases (sMMO)	$\text{C}_1\text{-C}_8$	Alkanes, alkenes and cycloalkanes	<i>Methylococcus</i>
Particulate Methane Monooxygenases (pMMO)	$\text{C}_1\text{-C}_5$	Alkanes and cycloalkanes	<i>Methylococcus</i>
Alkane hydroxylases (mostly AlkB)	$\text{C}_5\text{-C}_{16}$	Alkanes, fatty acids, alkyl benzenes, cycloalkanes	<i>Pseudomonas</i>
Bacterial P450 oxygenase system	$\text{C}_5\text{-C}_{16}$	Alkanes and cycloalkanes	<i>Acinetobacter</i>
Dioxygenases	$\text{C}_{10}\text{-C}_{30}$	Alkanes and polycyclic aromatic	<i>Acinetobacter</i>

The AlkB protein is the most studied alkane hydroxylase, whose function is to catalyze terminal hydroxylation of alkanes, generating n-alkanol and it requires iron and oxygen [59]. Other genes (*alkFGHJKL* cluster) are necessary to complete alkane degradation to fatty acids and gene order and regulation is quite diverse in natural environments [59–61]. The presence of transposase genes into the cluster is reported in some studies and indicates the spreading of gene cluster in nature and shows opportunities for evolutionary events [61].

1.7. Biofilms in the Petroleum Industry

The metabolic pathways in petroleum context go far beyond the degrading pathways showed in last topic. The genetic interactions concerning life around petroleum metabolism is indeed considered noble from the biotechnology point of view towards the development in bioremediation strategies. However, there is second class of high-level of importance microbial community: Biofilms [62, 63].

Biofilms are complex matrixes of microorganisms that adhere to each other over a surface, usually recruiting extracellular polymeric substances (EPS), so that layers within the biofilm with different patterns of gene expression are formed. In industry, the development of biofilms control strategies, because of the enhanced quorum-sensing activity, and the complexity of gene expression of over the film layers. Antibiotic resistance and toxic compound production, are some of the risks that biofilms can perform hindering efficiency of bioprocesses [64].

The petroleum industry encompasses the biofilm termination in two main categories: (i) those who promote novelties in bioremediation, usually related to bioprospecting of bacteria with the potential to be immobilized in supports for oil degradation, and (ii) the biofilms that hinder petroleum extraction, and cause structural damages to oil rigs, and by-products of petroleum [38].

Sulfate reducing bacteria (SRB), described initially in the last topic, are considered a major challenge in the industry of petroleum. Currently there are over 220 described species (most of the *Desulfovibrio* genus), mostly gram-negative as well as absolute anaerobes, that have been isolated from petroleum oilfields. Thus, they use sulfate (or other sulfur compounds, e.g., sulfites, thiosulfate, tetrathionate) in the respiration producing sulfide [62]. To that end, sulfide ions generated from reduction of sulfate reacts with water, producing hydrogen sulfide by SRB causes corrosive damages over the inner surface of oil ducts, generating one of the major issues off shore petroleum scene [38].

Communities of SRB have been described as one of the hardest to study. Since the environmental conditions of oil reservoirs usually are extremely challenging to be reproduced in the laboratory, microorganisms are often absolute anaerobes, the temperature and pressure in the reservoir are extreme, salinity and pH are. Considering that, novelties in molecular biology making use of 16S rRNA, sulfate reductase (*dsrAB*) genes, and metagenomic approaches have been fundamental to the understanding of the community diversity, composition, and genetic profile [16]. I.e., New techniques have demonstrated how different species of genus as *Desulfobacterium*, *Desulfotomaculum*, *Desulfobacterium*, *Desulfomicrobium*, and *Desulfobulbus* correlate with temperature, salinity, depth, and the concentration of other chemical compounds in the oil mixture, as acetate, propionate and sulfur levels [65].

1.8. Metagenomics for Marine Microbial Communities

The concept of metagenomics was defined by Jo Handelsman [66] as “the genomic analysis of a population of microorganisms” and encompasses molecular biology methods to directly access the genetic material of microbes from environmental samples [67]. The main advantage of using a metagenomic approach is to overcome the culture limitation, since only the minor (0,1-1%) part of the microbes are cultivable using the methods we know.

In the beginning of the 2000's, two main approaches for metagenomic analysis were preferred, and involved the total DNA extraction from samples, followed by (i) PCR, cloning and sequencing – the so-called amplicon approach, mostly the 16S rRNA gene - or (ii) fragmentation, cloning and sequencing – the shotgun approach. Using those methods, molecular microbiologists could (and still can) get a better understanding about microbial diversity and their interaction with the environment, host, human, plant and others.

In 2004, 454 Life Sciences (being acquired by Roche Diagnostics in 2007) has developed the first massively parallel DNA sequencing technology that were able to sequence thousands of DNA fragments in a single run, and it has eliminated the necessity of cloning. Several platforms for DNA sequencing were released after the Roche 454 being known as next generation sequencing (NGS) technologies and today we can achieve tens of billions of base pairs in single run that takes a few days long. The main characteristics of the most popular NGS platforms are shown on Table 3.

Combining the metagenomic approach with NGS, the microbial communities can be deeply analyzed in any environment. Marine environment covers approximately 70% of the Earth surface and hosts a huge amount of microbes ($> 3 \times 10^{30}$) and these microbes consists of bacteria, archaea, protists and fungi. Marine microbial communities play a key role on the global biogeochemical cycles of important elements, such as carbon, oxygen, nitrogen, phosphorus and sulphur [69]. Many studies have been made to determine which taxons are present in marine environment (mostly using 16S rRNA as phylogenetic marker), how they are distributed in space and time and the reaction to physical and chemical changes.

The marine microbial communities are represented by (i) phototrophic (in the upper layers), (ii) chemotrophic primary producers, (iii) denitrifiers, (iv) nitrifiers, (v) nitrogen fixers, (vi) archaea, (vii) heterotrophs. Photo and chemotrophic microbes obtain biomass from carbon dioxide (CO_2), but phototrophics obtain energy from light and chemotrophics from chemical reactions. Besides them, heterotrophic microbes can also be found, but they obtain biomass from carbon reduced and recycling nutrients. Denitrifiers, nitrifiers and nitrogen fixers are involved in the nitrogen biogeochemical cycle, where atmospheric nitrogen (N_2) is fixed by bacteria and is transformed to ammonia, nitrite and nitrate; ammonia can be oxidized into nitrite and nitrate by nitrifiers, and nitrate can be reduced to N_2 by denitrifiers. Viruses, protists, grazers and other organisms less abundant also compose the marine biomass, but are not the focus of this chapter.

It is known that microbial communities changes over time, space and environmental conditions. Fuhrman and colleagues have considered microbial changes occurring in four timescales – (i) hours, (ii) daily to weekly, (iii) monthly to seasonal and (iv) interannual. In hours, rare taxa can become abundant on the sea surface due to day-light cycle, to light, to rapidly cell death and maybe another reasons not yet documented but hypothesized [70]. Daily to weekly timescale can reveal how microbial communities reacts to environmental conditions (and changes), such as virus infection, weather, interaction with other microbes or larger

organisms, or even phytoplankton blooms. Solar angle, seasonal changes and nutrient availability influence microbial changes from monthly to seasonal periods. Interannual changes are caused by anthropogenic actions such as overfishing, global warming and pollution, as well as environmentally natural changes (e.g., Pacific Decadal Oscillation).

Table 3. NGS characteristics. Adapted from Braga and colleagues [68]

NGS Platform/Company	Read Length	Throughput
3730xl DNA Analyzer/Life Technologies (http://www.lifetechnologies.com/)	Up to 900 bp	690 – 2100 Kbases
454 GS FLX System/Roche (http://www.454.com/)	Up to 1000 bp	700 Mb
Illumina HiSeq 2500/Illumina (http://www.illumina.com/)	2 x 150 bp	150 – 180 Gb (Dual Flow Cell)
ABI SOLiD 5500xl/Life Technologies (http://www.lifetechnologies.com/)	75 bp (Fragments)	Up to 250 Gb
	75x35 bp (Paired-end)	
	60x60 bp (Mated-paired)	
Ion Torrent Personal Genome Machine/Life Technologies (http://www.lifetechnologies.com/)	Up to 400 bp	Up to 100 Mb (314 chip v2)
		Up to 1 Gb (316 chip v2)
		Up to 2 Gb (318 chip v2)
PacBio RS System/Pacific Biosciences (http://www.pacificbiosciences.com/)	Over 40,000 bp	Up to 1 Gb

Metagenomic has aided to get knowledge about the genetic diversity of marine microbes. A remarkable work made by Venter and colleagues (2004) estimated 1800 genomic species on the Sargasso sea, including 148 previously unknown bacterial phylotypes and 1.2 million of previously unknown genes [71]. Thirteen years late, many discoveries were done and we are able to couple metagenomics with other techniques like FACS (Fluorescent-Activated Cell Sorting), MDA (Multiple Displacement Amplification) to analyze single cell genomics (SCG) of marine microbes as reported in some studies [72, 73].

The use of SGC techniques is shining light on the called “microbial dark matter” (MDM), which is the major portion of the microbial diversity we are not able to cultivate and consequently do not know the function in the environment. Rinkle and colleagues (2013), on a notable article, have reported a novel amino acid use for the opal stop codon, an archaeal-type

purine synthesis in Bacteria and complete sigma factors (proteins that helps transcription) in Archaea similar to those in Bacteria [73].

Evolution is responsible for the great microbial diversity and the biotechnological potential of their enzymes are still under explored. The biotechnological potential of marine microbial enzymes is focus of important research areas. Proteases, lipases, polysaccharide-degrading and extremozymes (derived from microbes living on extreme environments) have been isolated from marine bacteria and archaea [74]. Biosurfactants and enzymes able to degrade hydrocarbons from petroleum are considered one of most searched (macro) molecules on the nature for its potential use in bioremediation process [44]. There are more than 79 bacterial genera able to use hydrocarbons as sole source of energy and carbon, many of them uncultured, and metagenomics can be a powerful tool if coupled to other techniques to get knowledge about these enzymes and bioproducts.

1.9. Microbiologically-Influenced Corrosion (MIC)

Corrosion can naturally occur in natural and artificial environments. Materials made by pure or mixed compositions of metals chemically decay in a process called oxidization. Corrosion is a electrochemical process which involves a anodic (metal 'A' ionization) reaction and a cathodic (metal 'B' reduction) reaction. Those reactions could be influenced by microbial action, primarily when microbial colonies arrange themselves in biofilms. It is well known that biofilm formation is one of the most problematic interferences caused in technological systems. The accumulation of growing biofilms in a given system that causes corrosion and further material decay is calling biofouling [75].

The microbial activity over the metal and semi-metal species is most catalyzed by many metabolism products such as enzymes, organic and inorganic acids, volatile compounds and exopolymers, which all potentially have influence on anodic/cathodic reactions over the exposed material. Those metabolites alter the electrochemical balance in the interface biofilm/metal leading to a gradual and constant corrosion. The corrosion lead by microbial action is known as biocorrosion or Microbiologically-Influenced Corrosion (MIC) [76]. The MIC is commonly due to bacterial accumulation, but can occur by fungal and algae as well [77].

The major organisms frequently involved in MIC processes are the sulfate reducing bacteria, the sulfur oxidizing bacteria, iron reducing/oxidizing bacteria, manganese oxidizing bacteria, organic acid and exopolimers synthesizing bacteria. Since 1930, the sulfate reducing bacteria is studied due to investigation about the corrosion of many metals and semi-metals. Also, the corrosion action of this class of bacteria is spread through land and water environments under aerobic and anaerobic conditions. Many models have been proposed in order to elucidate the mechanisms under such different corrosion processes [76].

The biofilm formation induces an oxygen gradient that can explain the oxygen concentration in the aerobic zones of a microbiologically-induced corrosion. When the MIC is occurring under anaerobic process at neutral pH, it is common to find sulfur reducing bacteria in the biofilms [78]. According to Aguiar [79] suggests that sulfur reducing bacteria are using three major pathways. The first pathway is a naturally occurring due to metabolic needs, whereas those bacteria use their surface hydrogenases to consume the cathodic H₂ film as a consequence of the electrons derivate from the metal ionization from the anodic end. In normal

conditions, the hydrogen formed in the cathodic end can be absorbed to the material resulting in polarization which slows the corrosion process. However, in the presence of sulfate reducing bacteria, the cathodic end is depolarized which increases the hydrogen consume locally, the reaction is shifted to deionized even more water molecules, resulting in increasing Fe^{2+} in solution, and so the metal decay reaction speeds.

The second pathway is also a direct way to corrosion. It occurs due to the metabolic products expelled by those bacteria, such as H_2S (hydrogen sulfate) which reacts with Fe^{2+} forming FeS (iron sulfate) which increases the H^+ concentration and so stimulating the electron consume in the cathodic end. In the case of biofilms, the reposition of hydrogen ions in the metallic surface can be seen as a cathodic repolarization of this surface which protects it from the corrosion. The third pathway is an indirect method occurring by the generation of oxygenized zones over the metal surface where specific metabolites are deposited [79]. Some studies argue that none of the pathways cited above are predominant over one another due to the quantity of factors involved in the process as a whole [80, 81].

The following electrochemical reactions describing the CIM process induced by sulfate reducing bacteria were suggested by van Wolzogen Kuhr and van der Vlugt in 1930 [82], as well as the global reaction describing the final process of depolarization of the cathodic end [77].

The corrosion of steel by sulfate reducing bacteria has a very characteristic pattern called pitting with pits, or small corrosion holes where the iron sulfate is deposited over time [83]. The characteristics of a corrosion pit are dictated by the physical and chemical corrosion products involved in the process after the oxygen has accessed this environment [81]. The general characteristics of corrosion process can be more related to the metabolic state of the bacterial cells over the total bacterial biomass adhered to the biofilms (9 - Beech et al., 1994). As described by Pedersen (1988) [78], the microbial species and the carbon source absorbed by these species are also very important parameters for regulation of the CIM process. As well, the exopolymers have their hole in the corrosion process since they allow the bacterial cells to group together irreversibly to the metal surface and provide protection to the bacterial cells against foreign hazardous molecules and other possible competitors [84].

Besides the fact that sulfate reducing bacteria are involved in corrosion process in petroleum extraction fields by the formation of biofilms and synthesis of corrosive metabolites, other group of bacteria needs to be acknowledged for contributing direct or indirectly for the corrosion of metal bonds [78]. Moreover, it is important to notice that in nature, many corrosion processes reflect directly the variety of microorganism involved in not in isolated processes, but in collaboration, with one serving on another in a particular environment [84].

The impacts caused by biofilms formation are estimated to be 1% of GNP (gross national product) of industrialized nations, where it is classified as an oversized process, biofilms and interruption of production expenses, and population health risk [75].

1.10. Microbial Control Methods Related to Oil Industry

The treatments usually used to control microbial growth, specially of the SRB group, and to mitigate damage processes associated to SRB presence in oil wells are mainly based on the inhibition of biologic activity (IBA) or on the specific prevention of anaerobic activity (PAA) [85]. In this last one, one strategy used that aims to prevent anaerobic activity through sulfate elimination from the aqueous phase is known as nanofiltration. This technic is based on water filtration using porous membranes (pore diameter of 1 mm, approximated). Comparatively, this membrane pores are slightly larger than reverse osmosis membranes one, and smaller than ultrafiltration membranes pores. When nanofiltration is applied, sulfate concentrations in sea water can be reduced from 2,700 ppm to less than 40 ppm. However, this technic is very expensive to be applied for large amounts of water as oil industry demands [86].

Considering IBA, the introduction of chemical biocides in injection water is commonly used in operational wells during waterflooding to prevent microbial growth. The biocides are divided as oxidative (chlorines and chloramines) or non-oxidative agents (amines, anthraquinones and aldehydes). The biocides that are more commonly used by petroleum industry are the anthraquinones, glutaraldehyde and the THPS (tetrakis hydroxymethyl phosphonium sulfate). The oxidative ones depend on factors such as light, pH and temperature to be effective. In the other hand, the non-oxidative are more stable in environmental conditions than the oxidative ones. Because of it, the non-oxidative can be used in a variety of environments [87].

The oil industry uses biocides to treat the petroleum recovery system, the pipelines, the tanks, the refrigerator tower, among others. The biocides effectiveness is the point here, since biocides treatments can cause bacterial resistance and it can also lead to environmental impacts. Because of this, the biocide type chosen for a specific treatment depends on the laws that dispose on environmental protection and on bacterial populations that are present in the field. Therefore, new strategies have been already considered to better control SRB presence, and their known consequences as biofilm formation, biocorrosion of equipment's and reservoirs acidulation [88, 89].

A variety of methods were proposed to inhibit SRB populations in the oil wells. Some of these methods, were based on microbial competition stimulation through favorable thermodynamically compounds introduction in the reservoir environment. These compounds, such as oxygen (O_2) and nitrate (NO_3), are electron acceptors more favorable than sulfate (SO_4) for heterotrophic metabolism in aerobic and anaerobic environments, respectively. Thus, when nitrate is introduced in an environment, the bacterial group known as nitrate reducing bacteria (NRB) are benefited. The SRB and the NRB competes directly for carbon organic compounds and, as sulfate reduction has a reduced energy gain when compared to nitrate reduction reaction, the NRB won this competition [90]. In summary, nitrate introduction is known as a competitive exclusion technology and it have been extensively studied [91–94].

Jurelevicius et al. (2008) observed nitrate effects in the SRB populations in a two-months experiment that consisted on the continuous introduction of nitrate in a water/oil storage tank.

Consequently, in the same study, the hydrogen sulfide production was controlled by nitrate injection. In another work, Marques et al. (2012) also observed nitrate injection effects in total bacterial community present in the produced water, in a three-months bioreactor experiment. In this study, SRB populations were reduced by nitrate injection but, in contrast, the metal corrosion enhanced with nitrate introduction during the experiment. As another disadvantage, Engelbrektson et al. [95] also highlights that nitrate needs to be injected in high concentrations in an intermittent way to directly inhibit SRB activity which commit logistical and economically the entire process.

As an alternative to nitrate introduction, Engelbrektson et al. [95] suggest the use of another electron acceptor, thermodynamically more favorable than sulfate (SO_4), the perchlorate. In this study, the authors observed that the perchlorate introduction led to a reduction in hydrogen sulfide production and the stimulation of sulfur oxidizing bacteria (SOB) populations. As some advantages, the authors point to the direct SRB-inhibition by perchlorate, the stability of this compound in the sulfide presence, and the absence of residual sulfide in the end of the treatment.

Another interesting alternative for SRB control, with less environmental impact than biocides, includes microbial-stimulating of antimicrobial substance producers (AMS) strains. This method could be used apart or as a complementation to the synthetic biocides. Some bacterial strains well-known as SAM producers are affiliated to Actinomycetes (Gram-positives filamentous bacteria) and spore-forming bacteria genera (*Bacillus*, among others). Korenblum et al. [96] observed that the strain H2O-1 affiliated to *Bacillus* genera, could produce SAM, classified as a surfactin-like, against a *Desulfovibrio alaskensis* strain. After that, da Rosa et al. [97] also demonstrated the inhibition of the same SRB by *Streptomyces lunalinharesii* 235 strain, another AMS producer. In another work, da Rosa et al. [97] demonstrated that *Streptomyces lunalinharesii* 235 strain could prevent the formation of SRB biofilm.

The natural products, or plant products, or bioproducts such as essential oils and the plants extracts can present antimicrobial activity against microorganisms. The essential oils (OE) are characterized as a mix of lipophilic volatile compounds produced by plants. The plants extracts are characterized as an herb/alcohol liquid solution, popularly known as popular medications. The natural products present low costs for industries, less environmental impacts, and they do not represent security and health risks for oil and gas employees. Thus, the bioproducts that presents antimicrobial activity against SRB represents another interesting alternative for the synthetic biocides [98].

Korenblum et al. [99] demonstrated that the OE of the lemon grass and its active compound, the cytral, showed antimicrobial activity against a *Desulfovibrio alaskensis* strain. In the same work, the OE and the cytral also presented an anticorrosive effect. Recently, de Souza et al. [100] demonstrated the antimicrobial activity of a variety of OE against a *Desulfovibrio alaskensis* strain and a bacterial consortium present in the produced water. The plant extracts SRB antagonistic activity was also demonstrated by Bhola et al. [101]. All these studies contribute to ensure the potential of the bioproducts for biotechnology application in the petroleum industry.

1.11. Bioremediation of Organic and Hydrocarbon Pollutants

One of the major oil spill is the Deepwater Horizon oil rig, in the Gulf of Mexico in 2010 [102–104]. At the time, the site became surrounded by oil, and the environmental impacts reached distances up to 2000 km of shoreline besides, the spill devastated many natural habitats. bioremediation was one of the key instruments to mitigate the environmental impacts and hazard in those depredated ecosystems [105, 106]. Bioemediation is a biobased, eco-friendly non-invasive strategy to remove ou degrade pollutants by using mostly microorganisms. Currently it's been considered it is also cheaper than conventional chemical methods, as chlorine usage and manipulation of highly oxidative agents [107].

One of the main strategies in the bioremeditation of alkanes is the aerobic pathway [108]. Alkanes, likewise plant paraffins and fatty acids have a ubiquitous profile in nature so that many microorganisms' metabolism use n-alkanes as carbon source. In this context, high Biological oxygen demand (BOD) is fundamental to the performance of two types of enzyme pathways: the monooxygenases, which take a straight forward strategy, seing that monooxygenase enzymes act by a incorportating oxygen atoms at terminal carbons of the linear alkanes chains, generating then primary alcohols. The second type of enzymes are the dioxygenases, are capable of inserting two oxygen atoms, forming now hydroperoxidades, instead of a primary alcohol. Insteringly, both enzyme pathways generate primary fatty acids as final products, opening up a diversified metabolic window (mostly go into the B-oxidation pathway) to microorganisms use it, e.g., cell wall composition, storage into lipid storage [108].

Bioremediation applications associated with hydrocarbons (e.g., petroleum, kerosene and crude oil) have showed robustness in terms of environmental diversity, as glaciers, mangroves, soil, and water [109, 110]. Crude oil removal by is one of the main activities in soil decontamination, with huge potential of scalability and development of novelties for *in situ* bioremediation [107]. Modern technical approaches have involved the development of mixed biofilms strains of *Pseudomonas monteilii* and *Gordonia* sp immobilized in polyurethane foam (PUF) as support for the biofilm and have been demonstrated a robust economic viability as a bioremediation tool [111, 112].

The biodegradation of petroleum hydrocarbons, however, faces major challenges usually concerning physiological requirements of microorganisms in *in situ* remediation [107, 113], where nitrogen and phosphate shortage have been reported as main contributors to biodegradation insucess in nutrient deploited environments [114]. In reference to that issue, permeable reactive barriers (PRB) have been used to minimize harzard and environmental impacts caused by diesel fuel spill in Casey Station, Antarctica. Techniques to mitigate the issue of nitrogen dependency, and cutting-edge approaches have involved the use of ammonium exchanged zeolite (sieves for ion exchange improvement) with PRB in the enhancement of biodegraation to support biofilm growth and sustainability of n-alkane degrading bacteria, as *Actinomycetales* and *Burkholderiales* [115].

1.12. Reservoirs Souring

The sulfur is one of the most important chemical elements from the earth and it is present in rocks as pyrite (FeS_2) and plaster (CaSO_4). The major reservoir of inorganic sulfur in our planet is in the ocean sediments where this element is found as sulfate ion (SO_4^{2-}). In these

sediments, the microorganisms play an important role to sulfur-cycling in anoxic areas and the sulfate reduction can be divided in assimilatory and dissimilatory reduction processes. In the first case, some microorganisms reduce sulfate in small amounts to incorporate sulfur in organic compounds to generate cysteine, methionine among others. In the last case, sulfate is reduced in large amounts, sulfide generated is cell-excreted, air oxidized and used by other organisms or complexed with metals forming metals sulfides. The dissimilatory sulfate reduction aims to generate energy for a bacterial group known as sulfide reducing bacteria (SRB) in their anaerobic respiration metabolism. In this process, a variety of electrons donors can be used for SRB, but the main ones are hydrogen, lactate and pyruvate [116, 117].

The SRB are directly involved in carbon-cycling in the anoxic sediments as they degrade carbon organic compounds using sulfate as the final electron acceptor producing hydrogen sulfide, in a reaction that requires eight electrons and a variety of intermediary stages. The dissimilatory process occurs in the cytoplasmic membrane, in the electron transport chain. In summary, the sulfate ion is activated in APS (adenosine 5'-phosphosulfate) by the enzyme ATP-sulfurylase. In the following, APS is reduced to sulfite by the enzyme APS reductase. Finally, the sulfite reductase enzyme catalyzes the sulfite reduction to sulfide. The sulfate is an electron acceptor less favorable than oxygen (O_2) and nitrate (NO_3) and, in response to the reduced energy gain of this reaction, it requires a low redox potential to SRB metabolism [117]. Besides, in sulfate absence, some SRB can use nitrate as the final acceptor or even some organic compounds as pyruvate [118].

The SRB diversity is related to their habitats which demonstrate the biological complexity of this bacterial group. In numbers, more than 220 bacterial species were affiliated to 59 SRB genera from Bacteria and Archaea domains [119]. The SRB genera described was *Desulfovibrio* and *Desulfotomaculum*, being this first one the most studied [117, 120]. The SRB are widespread, occurring in natural and artificial environments where sulfate is present. The SRB have already been isolated from marine and fresh water sediments, hydrothermal vents, volcano mud, microbial aggregates formed in hypersaline conditions, plants rhizosphere, aquifers among others. Furthermore, the SRB were also isolated from oil fields [116].

The microbial development in oil fields is limited by electron acceptors concentrations, such as oxygen, nitrate, ferrous metal or sulfate. The presence of sulfate ions inside the oil well creates an appropriate environment for SRB activity, which leads to hydrogen sulfide production, in a process known as reservoir souring [121].

The souring process is usually observed in offshore platforms where the sea water is used in the waterflooding process to enhance reservoir pressure and displace the oil from reservoirs rocks during the secondary recovery. The sea water contents high concentrations of salts, specially chlorates, sulfates and significant densities of viable SRB populations [122]. The sea water is collected from places nearby the platforms and submitted to several treatments, before it can be injected in the well. First, the water is treated to remove the oxygen to avoid pipeline corrosion process. After that, the water is filtered and a variety of chemicals are introduced in this fluid as antifoam agents, crusting inhibitors and sulfide and bisulfide ions, these last ones added to water to interact with dissolved oxygen forming sulfate [123, 124].

The sea water after treatment is known as injection water. The injection water is injected in the well and mixes with formation water, that consists on a residual fluid generated during the quarry development process. The result of the injection and the formation water combination is the production water [125]. This last one is collected with the oil in the production well in the end of the waterflooding. The production water is characterized as a

water/oil emulsion, which is rich in electron donors, carbon sources (acetate, propionate among others), nitrogen sources (such as ammonia) with higher salinity than sea water (chlorates and bicarbonates high concentrations). The produced water is re-injected in the well several times during the waterflooding process before it can be discarded [126, 127].

The produced water contains high concentrations of sulfate ion and an even higher density of viable SRB populations than that one present in sea water. The re-injection process with produced water contributes to reservoir souring since this fluid brings the preferential electron acceptor in SRB anaerobic respiration (sulfate), the SRB population in high densities and organic compounds (hydrocarbons present in water and/or in the well) used in SRB heterotrophic metabolism. Moreover, the waterflooding cools the reservoir reaching lower temperatures and providing the perfect environment for SRB development as they are mesophilic bacteria. Consequently, the SRB present in produced water can generate hydrogen sulfide in extremely higher concentrations [119, 128, 129].

The hydrogen sulfide is responsible for several economic losses for the petroleum industry. The hydrogen sulfide leads to oil, gas and produced water contamination, reducing the petroleum quality. To promote produced water re-injection, the iron sulfide generated from SRB metabolism needs to be removed from the aqueous phase and it implicates in more financial costs. The waterflood oil yield is also affected by the iron sulfide as it can lead to reservoir-plugging, reducing the rock permeability. The sulfide gas is toxic, inflammable and represents a potential risk for employee's security and health as well. Consequently, an oil well acidulation involves additional costs to control employees' sulfide-exposition. Besides, extra costs concerning souring-control and prevention also count. Such mechanisms involve: i. Chemical treatments to remove sulfide; ii. Transport and storage requirement to treat contaminated materials; iii. Biocides introduction; among others. All these mechanisms cause major logistical implications for the oil business [89, 130].

According to Davidova et al. [131], the oil reservoirs are not the only and nor even the more affected ones by the sulfide production in the petroleum fields. The sulfide production and SRB activity also causes clear damages as the corrosion of equipment's surface as water/oil storage tanks or ponds, pipelines among others. The corrosion process leads to a variety of economic problems for the petroleum industries. The National Association of Corrosion Engineers (NACE - guideline MR0175/ISO-15156) establish that sulfide gas partial pressure cannot exceed the oil facilities resistance level. In case of it, the oil industry is responsible to take some security measures adopting sulfide corrosion protection services. These services can result in millions of dollars of additional costs for each well, and therefore for the entire oil drilling, extraction and recovery [124, 89, 130].

CONCLUSION

Petroleum exploration is one of the most important activities in the world and has several issues to be comprehended. Microbes have an essential role in many steps, since formation, until in eventual process of environmental cleaning. Understanding microbial genetics and how they interact with oil and environment is crucial to improve exploration and for the so-called one health care.

Chapter 74

ESTROGEN ACTIVATED ERs ARE THE CHIEF GENETIC SAFEGUARDS OF SOMATIC AND REPRODUCTIVE HEALTH IN MAMMALIANS

Zsuzsanna Suba*

National Institute of Oncology,
Surgical and Molecular Tumor Pathology Center,
Budapest, Hungary

ABSTRACT

In healthy individuals, the incessant activity of regulatory genetic mechanisms ensures the metabolic and proliferative equilibrium of cellular activity. In case of accidental defects occurring in any part of the system, a coordinated counteraction of numerous mediators may successfully help in the restoration of physiologic processes by means of either overexpression or hyperactivity. Even serious defects of genome stabilizer mechanisms may be kept in balance for a long duration, showing the clinical signs of good health. By contrast, due to the exhaustion of the compensatory processes, DNA defects may develop and lead to the clinical manifestations of diseases. Estrogen activated estrogen receptors (ERs) are the primary initiators and organizers of the up-regulatory circle of genome stabilization in correlation and crosstalk with aromatase enzyme and genome safeguarding proteins, such as BRCA_s. The promoter regions of *ESR1*, *BRCA1*, and *CYP19* aromatase genes exhibit strong triangular partnership for the harmonized regulation of the synthesis of ERs, BRCA proteins and aromatase enzyme, which can be reconstructed from the meticulous details of earlier scientific results. Considering the extreme capacities of ER-signaling for self-restoration, it is obvious that antiestrogen treatment, either ER binding by a false ligand or inhibition of estrogen synthesis, may provoke extreme compensatory actions in genetically proficient cases. Analyses of the results of genetic studies on tumor cells have shown that upregulation of ER-signaling induced by natural estrogen or antiestrogen is a beneficial defensive process even in tumor cells, promoting their domestication and elimination. A schematic representation of the main stream of

upregulative genome stabilizing circle visualizes the possibilities for extreme counteractions against the toxic effects of antiestrogens. The presented complex genome stabilizer mechanisms reveal that cancer cells may preserve their residual capacity for the upregulation of ER-signaling, even if the efforts are not satisfactory.

Keywords: activating mutations, antiestrogen resistance, apoptotic tumor cell death, artificial estrogens, breast cancer, cancer prevention, cancer therapy, DNA-repair, estrogen therapy, long non-coding RNAs

INTRODUCTION

A direct correlation between serum estrogen concentrations and breast cancer development was erroneously supposed and both epidemiologic and experimental studies tried to justify this preconception [1, 2]. Nevertheless, the controversial data of serum estrogen levels observed in breast cancer cases could not support the principle of estrogen induced carcinogenesis in either premenopausal or postmenopausal patients [3]. Moreover, estrogen withdrawal as an anticancer therapy could not equivocally inhibit the progression or recurrence of mammary tumors as it was expected [4].

These results seemed to show that highly complex regulatory failures may act in the background of tumor development instead of elevated estrogen concentrations [4, 5]. Despite all contradictory experiences, hypoestrogenism as an anticancer measure gained great popularity in medical practice and this misbelief led to a long-lasting erroneous pathway of breast cancer therapy throughout the 20th century, until now.

In the early 70s, tamoxifen, a synthetic ER-blocker was introduced for the treatment of ER-positive breast cancers [6]. Tamoxifen treatment resulted in low anticancer effectiveness similarly to earlier endocrine therapies, causing frequent and unexpected toxic effects, such as thromboembolic complications, stroke and malignancies particularly in the endometrium [7]. Later on, endocrine manipulations were introduced for the inhibition of estrogen biosynthesis by means of aromatase inhibitors [8]. Aromatase inhibition exhibited low effectiveness against breast cancer and frequently induced high toxicity in the targeted estrogen deficient postmenopausal breast cancer cases [9].

These failed efforts of medical practice and the pharmaceutical industry explain the confusion later experienced in association with the effects of synthetic estrogens and antiestrogens. Both types of compounds may transiently promote compensatory upregulation of ER signaling and tumor regression in short-term experiments, but unfortunately, long term treatment was seen to evoke toxic symptoms and tumor growth [10]. By contrast, natural estrogens show no toxicity and their advantageous anticancer effects are strengthened by higher doses [11]. All synthetic manipulators of ER-signaling are dangerous poisons that block ER-activation, while mimicking estrogenic activity by means of transient extreme compensatory increase of estrogen signaling. [10, 12].

In genetically proficient patients, upregulations of ER activity and estrogen synthesis caused by antiestrogens may evoke temporary strong anticancer defense mechanisms, while simultaneously promoting spontaneous tumor cell death. By contrast, in the majority of patients with mild to severe genetic disorders, antiestrogen administration induces a weak counteractive

increase of both estrogen synthesis and ER expression, which is not sufficient for restoring anticancer defense mechanisms and tumor growth inhibition [10].

Based on the lessons learned from the four decades of antiestrogen therapy, the chaotic manifestations of artificial ER-inhibition together with the encountered activating mutations aiming to restore ER-signaling have helped to disclose the exquisite significance of estrogens in human health [13].

FUNDAMENTAL ROLES OF ER SIGNALING IN THE PHYSIOLOGY OF MAMMALIANS

Over the past decades extensive knowledge has been gained on the complex regulatory functions of estrogen activated ERs in regard to the safeguarding of somatic and reproductive health in mammals. ERs activated by estrogens may act as a hub where all physiologic molecular pathways converge, allowing harmonization of their transcriptional activity in tune with all cellular functions [14].

Estrogens are synthesized by aromatase enzyme via conversion androgens to estrogens. Estradiol (E2) is the most potent and abundant estrogen in the circulation, while estrone (E1) and estriol (E3) have weaker estrogenic activities. Two estrogen receptor isoforms, ER-alpha and ER-beta are members of the nuclear receptor superfamily and they exhibit strong crosstalk and interplay. ER-beta is mainly responsible for cellular enlargement, while the role of ER-alpha is crucial during the course of cell proliferation [15]. Both ER isoforms are mandatory regulators of cellular glucose uptake since cell growth and mitotic activity require an appropriate supply of fuel for increased metabolic processes [16, 17]. Defective estrogen signaling induced by either estrogen deficiency or ER resistance leads to cellular insulin resistance [3, 18].

ER-alpha and ER-beta proteins are expressed via transcriptional activities on *ESR1* and *ESR2* genes. Estrogen bound ERs may directly operate as ligand activated transcription factor proteins on the various promoter regions of target genes. ERs can also regulate gene expression through indirect binding to deoxyribonucleic acid (DNA) via interaction with transcription factor proteins. Moreover, cell membrane associated ERs may also confer non-genomic signaling cascades to estrogen dependent target genes. Ligand independent activation of ERs can also be induced by mitogen-activated protein kinase (MAPK) or protein kinase B (Akt) pathways. Finally, genomic and non-genomic pathways of estrogen receptor signaling converge on the target genes [14].

The transcriptional activity of ERs partially results in the expression of protein coding ribonucleic acids (RNAs), whilst the vast majority of RNA transcripts are non-coding RNAs (ncRNAs) [19]. Protein coding RNA transcripts of ERs may define the synthesis of enzymes, receptors and further regulatory proteins. By contrast, ER-induced long non-coding RNA (lncRNA) transcripts are capable of promoting epigenetic gene modifications via their specific chromatin remodeling activities resulting in necessary mutations on targeted genes [20]. lncRNAs are in close interrelationship with genome stabilizer proteins, such as p53, suggesting a pivotal role of these transcripts in the promotion of genome protecting mutations [19].

Estrogens are outstanding hormones exhibiting a strong, unique upregulative feedback mechanism with their own receptors. Both low and high estrogen levels drive the increased

expression and transcriptional activity of ERs so as to restore or augment cellular ER signaling. In turn, both low and high ER expressions require upregulated estrogen synthesis for the improvement or augmentation of crucial estrogen signaling [11].

Upregulation of estrogen signaling displays a unique dichotomy through genomic stabilization, ensuring the survival and safe proliferative activity of healthy cells, while inducing spontaneous death of malignant tumor cells [13]. Both protein coding and chromatin modifier RNA transcripts of ERs may have crucial roles in the genome stabilizer machinery.

ER-SIGNALING IS IN STRONG MUTUAL CORRELATION WITH DNA STABILIZER GENES AND THEIR PROTEIN PRODUCTS

Estrogen activated ERs induce transcriptional activities on numerous estrogen regulated genes, which are responsible for the metabolic and proliferative functions of all cell types. The complexity of regulatory processes allows for estrogen-liganded ERs to choose the temporarily most suitable coregulators, promoter regions and transcriptional pathways in harmony with the optimal safeguarding of DNA replication [11].

CORRELATIONS BETWEEN ER-SIGNALING AND THE BRCA SYSTEM FOR SAFE DNA REPLICATION

BRCA1 and *BRCA2* genes have been implicated in a number of pivotal cellular functions and may be regarded as safeguards of the genome. Their ubiquitously expressed *BRCA1* and *BRCA2* protein products control DNA-replication including transcriptional processes and recombination as well as repair of DNA damages [21].

BRCA-gene mutation is associated with defects in ER-receptor expression as well as DNA safeguarding [11, 22]. The failure of genome stabilizing *BRCA*-proteins is a promoter of cancer development with specificity for highly estrogen dependent female breast and ovary [23, 24]. In *BRCA* mutation carriers, the exhibited compensatory upregulation of non-liganded ER signaling [25] may strongly reduce the risk of cancer development [11].

THE CIRCULAR FUNCTIONAL MAINSTREAM OF THREE CRUCIAL GENETIC UNITS INVOLVED IN MAINTAINING GENOMIC STABILITY

In healthy individuals, the incessant activity of regulatory genetic mechanisms ensures the metabolic and proliferative equilibrium of cellular health. In case of accidental defects occurring in any part of the system, a coordinated counteraction of numerous mediators may successfully help in the restoration of physiologic processes by means of either overexpression or hyperactivity. Even serious defects of genome stabilizer mechanisms may be kept in balance for a long duration, showing the clinical signs of good health. By contrast, due to the exhaustion

of the compensatory processes, DNA defects may develop and lead to the clinical manifestations of diseases [11].

Estrogen activated ERs are the primary initiators and organizers of the up-regulatory circle of genome stabilization in correlation and crosstalk with aromatase enzymes and genome safeguarding proteins, such as BRCA1. The promoter regions of *ESR1*, *BRCA1*, and *CYP19* aromatase genes exhibit strong triangular partnership for the harmonized regulation of the synthesis of ERs, BRCA proteins and aromatase enzyme, which can be reconstructed from the meticulous details of earlier scientific results [11, 13].

Considering the extreme capacities of ER-signaling for self-restoration, it is obvious that antiestrogen treatment, either ER binding by a false ligand or inhibition of estrogen synthesis, may provoke extreme compensatory actions in genetically proficient cases [10]. The upregulative genome stabilizing circle may be induced by antiestrogens; either ER blockers or aromatase inhibitors. In our model, the well-known *BRCA1* gene and its protein product represent all other genome stabilizing systems, which presumably exhibit similar mutual partnership with the expressions and transcriptional activities of ER-alpha and aromatase enzyme [26].

I. Transcriptional Activities of ESR1 Promoter Regions

The increased expression and activation of the *ESR1* gene are the main drivers of genome stabilizer mechanisms in both estrogen deficient and ER-resistant states.

Activated ER-alpha assembles the most effective coactivators and occupies the available *ESR1* promoter regions. The increased transcriptional activity of ER-alpha induces high expressions of protein coding ER-alpha-mRNAs and leads to a self-generating overexpression of ER-alpha synthesis [11].

At the same time, a number of activated ER-alphas occupy the promoter regions of long non-coding RNAs (lncRNAs), e.g., *HOTAIR*, which are ER responsive [27]. Highly expressed lncRNAs are capable of provoking epigenetic changes on targeted *ESR1* promoter regions resulting in activating mutations. Newly formed activating mutations of *ESR1* genes may lead to the overexpression and increased estrogen binding capacity of ERs in an estrogen deficient milieu [28]. Abundant lncRNA transcripts of ERs are capable of inducing beneficial activating mutations on *BRCA1* promoters for the upregulation of DNA-stabilization [29, 30].

During physiologic cell proliferation the increasing expression of ER-alpha strongly upregulates aromatase synthesis and leads to increased estrogen production [11]. There are no literary data supporting the capacity of activated ER-alpha to occupy the *CYP19A* promoter region and induce increased aromatase enzyme expression. It is likely that under physiologic conditions, ERs choose the safe circular pathway that induces increased aromatase expression through the activation of *BRCA1* protein for the achievement of appropriate estrogen synthesis [13].

On the contrary, it has been shown that in breast cancer cells lines, estradiol treatment can induce rapid increases of aromatase expression and activity by a nongenomic activation of ER-alpha via crosstalk with growth factor mediated pathways [31, 32]. The quick upregulation of ER-alpha displays the existence of short nongenomic autocrine loops between ER-alpha and

aromatase enzyme synthesis providing rapid increase in estrogen formation in the emergency situations of malignant tumors [13].

II. Transcriptional Activities of *BRCA1* Promoter Regions

Activated ERs have the capacity to occupy the *BRCA1* promoter regions owing to the fact that *BRCA* genes are ER-alpha responsive [23]. Increased expressions of protein-coding *BRCA1* mRNAs and elevated *BRCA1* protein synthesis are driven by ER overexpression and high transcriptional activity, ensuring the adequate safeguarding of DNA-replication [11]. In turn, *BRCA* protein abundance promotes the expression of *ESR1*, the gene of ER-alpha [22].

Newly formed, abundant *BRCA1* proteins are able to occupy the lncRNA promoters and also to increase the expression of lncRNA. The abundance of lncRNAs may provoke beneficial epigenetic changes on *ESR1* promoters causing activating mutations that result in increased ligand-activated and ligand-independent activations of ER-alpha [25, 33, 34]. Further, lncRNA transcripts of *BRCA1* may stimulate chromatin modifications on *CYP19* aromatase promoter genes and may induce highly increased aromatase synthesis and estrogen production [35, 36]. Moreover, *BRCA1* protein stimulated expressions of certain lncRNA transcripts confer activating mutations on *BRCA1* genes, ensuring greater effectiveness of newly formed *BRCA1* proteins on DNA safeguarding.

Multiple transcriptional activities of the genome stabilizer *BRCA1* protein seem to be responsible for the key balance between the expressions and activities of ER-alpha and the aromatase enzyme.

III. Transcriptional Activities of *CYP19* Aromatase Promoter Regions

Increased *BRCA1* protein expression provides the opportunity of the considerable occupancy of *CYP19* aromatase promoter genes, which are responsive to *BRCA1* protein. Increased expression of the protein coding A450 mRNA results in upregulated synthesis of the aromatase enzyme capable of converting androgens to estrogens. Increased estrogen concentrations bind and activate abundant amounts of ER-alpha, further stimulating the upregulative circle of genome stabilization [11].

lncRNA promoter activation and increased lncRNA transcription by the *BRCA1* protein may lead to activating mutation of the *CYP19* aromatase gene in order to increase aromatase synthesis and estrogen production. In *BRCA1* mutation carriers, *BRCA1* protein activity confers the selection of the appropriate *CYP19* aromatase promoter region for the compensatory intensifying of estrogen synthesis [36].

The compelling symmetry and safety of the regulatory processes are suggestive of the fact that in turn, lncRNA transcripts of the A450 aromatase protein exert a backward upregulative feedback mechanism on the *BRCA1* promoter, aiming to activate the *BRCA1* protein synthesis [13]. There are however, no available literary data that would justify the existence of this retrograde regulatory pathway.

UPREGULATIVE AND DOWN-REGULATIVE CROSSTALK BETWEEN ER-ALPHA AND BRCA1 IN PHYSIOLOGIC AND MALIGNANT CELL PROLIFERATIONS

During rapid physiologic cell proliferation, as in case of pregnancy, the increased levels of estrogens are capable of upregulating the expressions of protein coding ER-alpha mRNA transcripts and ER-alpha synthesis [37]. Meanwhile, the high ER-alpha levels upregulate the expressions of protein coding BRCA1 mRNA transcripts as well as BRCA1-protein synthesis, with the outcome of an increase in DNA stabilization [38, 39]. In turn, high BRCA1-protein levels cause further upregulation in ER-alpha expression [40] and estrogen synthesis by way of the increasing expressions of both protein coding A450 mRNA transcripts and aromatase enzyme synthesis [36]. This upregulative circle ensures strong DNA-protection for the estrogen activated ER-determined rapid proliferation and differentiation of maternal and fetal cells, whilst inducing apoptotic death in spontaneously initiated malignant cells [11].

In contrast, malignant cell proliferation manifests a self-repressing mutual down-regulation of the low and/or defective expressions of ER-alpha and BRCA1-protein [11]. Mutagenic alteration or decreased expression of ER-alpha suppresses the expression of BRCA1 mRNA transcripts and BRCA1-protein synthesis; inhibiting appropriate DNA-safeguarding [39]. In turn, decreased or defective synthesis of the BRCA1-protein leads to down-regulation of both ER-alpha mRNA expression and ER-alpha synthesis and suppresses ER-alpha signaling [41]. The down-regulative circle results in unrestrained proliferation of poorly differentiated tumor cells, which is attributable to the defect of ER signaling and the feeble control of DNA replication [11].

Moreover, the two key proteins, ER-alpha and BRCA1, are also capable of direct binding, thus mutually regulating their activities as transcriptional factors. Certain binding sites drive the upregulation of each other's transcriptional activity, while others may silence the transcriptional processes [40].

In sum, it could be established that in patients with cancer, the upregulation of ER-signaling by estradiol treatment may be the main target for the restoration of the physiologic circle of cell proliferation and controlled DNA replication [12].

TUMOR CELLS EXHIBIT REMNANTS OF THE MACHINERY OF GENOME STABILIZATION PROVIDING CIRCUMSTANCES FOR SELF-DIRECTED DOMESTICATION AND ELIMINATION

Estrogen induced upregulation of ER signaling is a beneficial process even in tumor cells, promoting their domestication and spontaneous death, whilst in case of antiestrogen administration the activation of ERs is a compensatory action in order to strengthen the remnants of genome stabilizer processes [10]. Tumor cells are capable of self-sacrifice by means of increasing the expression and activity of both ERs and the aromatase enzyme.

Intratumoral production of aromatase and estrogens was demonstrated in both cancer cells and stromal cells as well as in adipocytes adjacent to breast tumors [42, 43]. Increased aromatase activity and high in situ estrogen concentration were demonstrated at the invasive

front of cancers, where tumor-stromal interactions may define the spread or regression of cancer cells [43]. Close correlations were observed between the intense aromatase synthesis of invasive breast cancer cells and neighboring adipocytes supporting the fact that high estrogen concentration is a defensive action against the invasion of tumors even when it fails to perform a satisfactory blockade [44, 45].

Estrogen treatment has been observed to increase ER expression in tumor cells. A study was conducted involving two estrogen receptor-positive breast cancer cell lines, which were treated by four types of estrogens: estrone, estradiol, estriol, and estetrol. It was found that all four provoked significant increases in ER-expressions as compared with the untreated controls [46].

In an ER-alpha positive breast cancer cell line, estradiol treatment increased both the expression and transcriptional activity of membrane associated ER-alpha via the phosphatidylinositol 3-kinase (PI 3-K)/Akt system. At the same time, the expression and activity of nuclear ER-alpha was also enhanced by the estradiol activation of Akt [47].

Insertion of exogenous ERs into an ER-negative breast cancer cell line was shown to activate a number of estrogen-regulated genes, and treatment with estrogen led to a decrease in the invasive and metastatic potential of tumor cells [48]. This finding was the first experimental testimony of estrogen induced tumor regression.

In tumor cells, estrogen activated ERs are capable of upregulating aromatase expression. When ER-negative SK-BR-3 cells were transfected with ER alpha, aromatase activity was elevated by estradiol treatment in a dose-dependent manner. In breast cancer cells, estradiol may upregulate the expression of aromatase enzyme by a nongenomic activation of ER-alpha via growth factor-mediated pathways [31]. Estradiol may also upregulate aromatase activity in breast cancer cells by means of enhanced tyrosine phosphorylation of the enzyme mediated by c-Src kinase [32].

In situ (intracrine) formation of active sex steroids at the sites of their actions from biologically inactive precursors in the circulation have been demonstrated to play very important roles in neoplasms. In breast cancer cases, a direct correlation was observed between the aromatase activity of tumors and survival after relapse [49]. Extreme aromatase positivity of tumors showed a significant correlation with tumor grade suggesting that the higher the histologic grade of tumors, the stronger is the need for defensive estrogen synthesis. ER-alpha positive metastatic breast cancer cells demonstrated increased intracrine aromatase synthesis even after entering the blood and lymph circulation [50]. In advanced tumors, aromatase synthesis and increased estrogen concentrations provide a feeble, final possibility for the restoration of the genome stability even before the death of patient.

In breast cancer cell lines, long-term estradiol withdrawal resulted in estrogen hypersensitivity mediated by highly increased ER-alpha expression. The hypersensitive tumor cells were able to react to estrogen levels at concentrations 2-3 logs lower than required to stimulate wild type cells [51]. Acquired estrogen hypersensitivity of ER-positive tumor cells is a justification that tumors may have partially preserved or even overexpressed DNA stabilizer capacities in strongly estrogen deficient milieu [11].

Spontaneous *ESR1* gene amplification is frequent in breast malignancies. Ninety-nine percent of tumors with *ESR1*-gene amplification detected at 6q25, showed estrogen receptor protein overexpression, compared with 66% of cancers without *ESR1* amplification [52]. These observations are the manifestations of the aptitude of tumor cells to upregulate ER synthesis by means of activating mutation in the *ESR1* gene.

Overexpression of mutation activated ERs was observed in association with the proliferative activity of advanced tumors, which was mistakenly regarded as a causal factor of resistance to tamoxifen treatment [53]. In reality, the exhaustive tamoxifen treatment performed in these cases blocked all the newly formed abundant amount of ERs despite the activating mutation of the *ESR1* gene [10].

ER-alpha is capable of increasing BRCA1 protein expression even in tumor cells, since the *BRCA1* promoter is ER responsive. In MCF-7 tumor cells, a delayed upregulative expression of BRCA1 protein was achieved by estrogen treatment. The peak value was reached after 24 hours, considering that new protein synthesis takes a long time [29]. In turn, it was found that the BRCA1 protein promotes *ESR1*-gene activation and transcriptionally upregulates ER-alpha mRNA and ER-alpha expressions in breast cancer cell lines [22].

In tumor cells, ERs activated by estradiol treatment mediate the transcriptional regulation and increased expression of lncRNAs [27]. It was demonstrated that HOTAIR, a lncRNA is pervasively overexpressed in most human cancers compared with noncancerous adjacent tissues [54]. HOTAIR expression was found to vary widely in primary breast cancers [55]. Patients with high HOTAIR expression were found to have lower risks of relapse and mortality than those showing low HOTAIR expression [55]. DNA methylation was observed in association with unfavorable characteristics in tumors and HOTAIR expression was strongly increased with the methylation level of DNA.

These results suggest that in malignancies, the estradiol induced expression of lncRNAs is associated with epigenetic changes in both *ESR1* and *BRCA1* genes, with the aim to promote ER-alpha upregulation, DNA restoration and tumor remission.

CLINICAL DATA ON TUMOR RESPONSES TO ANTIESTROGEN TREATMENT

ER blockade induced by tamoxifen therapy is a potent activator of estrogen synthesis and the consequential hyperestrogenism [10]. It was demonstrated in premenopausal breast cancer patients that tamoxifen, as the single therapeutic agent, increased the circulating levels of estradiol, estrone, and progesterone 2-3 fold [56]. The found local estradiol concentrations in the breast tissue of tamoxifen-treated premenopausal women were 8.2 times higher than the levels observed in case of healthy, normally cycling women [57]. These experiences support the concept that in tamoxifen-treated women, highly elevated serum and mammary estrogen concentrations are the possible inducers of transient tumor response [10].

In the later stage of tamoxifen treatment, ovarian cysts and amenorrhoea were detected in almost half of the tamoxifen-treated premenopausal breast cancer patients, whilst serum E₂ levels were observed to be highly elevated [58]. In these symptomatically estrogen resistant patients, even the extremely elevated estrogen levels were not enough to protect the ER signaling against the advanced ER blockade of tamoxifen. Development of ovarian cysts was not induced by the erroneously presumed toxic effects of the elevated estrogen levels; but rather the advanced ER blocking effect of tamoxifen led to the pathology of ovaries [10].

Exhaustive tamoxifen treatment has been found to cause severe, frequently life-threatening toxic effects in women, including thromboembolic complications, stroke, myocardial infarct and malignancies at various sites, with particular regard to endometrial cancer [59]. These toxic

effects are mistakenly attributed to unfavorable estrogenic actions, whilst being the typical complications of subtotal artificial ER blockade [10].

Tamoxifen-induced tumor responses cannot simply be defined by elevated estrogen synthesis, considering that maintenance of ER transcriptional activity and concomitant breast cancer regression require appropriate amounts of available ERs. The high estrogen receptor content of breast cancers has been shown to demonstrate significant correlation with prolonged survival in case of tamoxifen-treated pre- and postmenopausal patients [60].

In aromatase inhibitor treated postmenopausal breast cancer patients, plasma estradiol concentrations were found to be much higher than expected, despite the noted extensive interindividual variations in increased estradiol levels [61]. These observations justify the diverse capacities for compensatory aromatase synthesis and explain the great differences between tumor responses manifested among those patients who were treated with aromatase inhibitors [10].

Among women with breast cancer, a significant direct correlation was observed between the aromatase activity of tumors and patient's survival time after relapse [49]. In young premenopausal breast cancer cases, clinical control and examination of removed tumor samples revealed that the absence of CYP19-aromatase activity carried a significantly high risk for local tumor recurrence and poor prognosis [62]. The higher the compensatory aromatase synthesis and estrogen production in breast cancers treated with aromatase inhibitor, the better is the tumor response and prognosis of the disease.

In conclusion, the tumor responses among antiestrogen treated patients are with certainty defined by the genetic capacity of the individual cases for strong upregulation of ER expression and estrogen synthesis against highly toxic medicaments.

EXPERIMENTAL DATA ON TUMOR RESPONSES TO ANTIESTROGEN TREATMENT

In antiestrogen treated tumors, the compensatory increase in ER expression and aromatase enzyme via activating mutations assists the domestication and self-directed elimination of tumors as well as the survival of patients [13].

In tumor cells, long-term aromatase inhibitor-induced estradiol deprivation causes a four to tenfold up-regulation of the amount of ER α and a strong increase in the basal transcription level of several estradiol stimulated genes. On the other hand, the rapid, ligand independent activation of ERs further enhances adaptive estrogen hypersensitivity by means of an increased utilization of plasma membrane mediated pathways, including the activation of MAP kinase as well as PI-3-kinase and mTOR [63].

ER-positive breast cancer cells may adapt to an estrogen deficient environment via the increased expression of noncoding RNAs, which may perform epigenetic activating changes on the *ESR1* gene locus, with an abundance of ER overexpression as a result [28].

In antiestrogen resistant MCF-7/Ral tumors, long-term tamoxifen or raloxifene treatment continuously stimulated ER expression, while the growth of tumors was strongly progressive. Following a 5-week estradiol treatment, estradiol statistically significantly reduced the size of tumors earlier stimulated by raloxifene or tamoxifen pretreatment [64]. These findings indicate that the exhaustive administration of ER-blockers increases ER expression in tumor cells, while

ER blockade by a false ligand decreases the accessible receptor mass and promotes the growth of tumors. By contrast, estradiol treatment of antiestrogen resistant tumors may induce tumor regression by the extreme upregulations of both ER expression and transcriptional activity [10].

In ER-positive breast cancers, the increased level of *ESR1* mRNA was the strongest linear predictor of benefit from tamoxifen, whilst a low level of *ESR1* mRNA expression was a determinant of tamoxifen resistance [65]. Activating *ESR1* mutations in tumor cells were shown to result in constitutive activity and continued responsiveness to antiestrogen therapies in vitro [66]. Moreover, in breast cancer patients, adjuvant tamoxifen monotherapy resulted a significantly longer survival time for women with cancers exhibiting strong *ESR1* gene amplification [52].

On the contrary, activating *ESR1* mutations seemed to be a key event in the aggressive behavior of antiestrogen treated tumors [67]. In reality, in case of progressive tumors showing activating *ESR1* mutation even the defensive increase in ER expression is not enough to protect against the advanced ER-blockade of exhaustive antiestrogen therapy.

In breast cancer cell lines, long-term tamoxifen exposure strongly increased aromatase promoter activity and aromatase expression via G-protein-coupled receptor GPR30/GPER [68]. Abundance of aromatase synthesis and high estrogen concentrations may be persistent even in the exhaustive phase of tamoxifen treatment, although they are not satisfactory for the reactivation of near completely blocked ER signaling.

In conclusion, the activating mutations of ER-positive tumor cells against estrogen loss or ER-blockade may be attributed to the remnants of genome stabilizer processes to achieve self-directed tumor death instead of to an aggressive willpower for tumor survival [13].

CONCLUSION

The erroneous practice of using antiestrogens over the long term has revealed that the majority of women with less than optimal genetic reserve capacities do not respond well to antiestrogen treatment, which experience however has mistakenly been regarded as a de novo antiestrogen resistance. Even among genetically proficient breast cancer cases that show good tumor response initially, long-lasting antiestrogen treatment leads to the exhaustion of compensatory mechanisms with manifestations of toxic symptoms and progression of the disease. This phase is erroneously regarded as acquired antiestrogen resistance, but instead it is rather an almost complete blockade of ER-signaling.

Analyses of the results of genetic studies on tumor cells have shown that upregulation of ER-signaling induced by natural estrogen or antiestrogen is a beneficial defensive process even in tumor cells, promoting their domestication and elimination. The presented scheme of complex genome-stabilizing mechanisms demonstrates that cancer cells may preserve their residual capacity for the upregulation of ER-signaling, even if the efforts are not satisfactory. Activating mutations affecting ER functions have key roles in both the genome stabilizer machinery of healthy cells and the restoration of altered genetic pathways of DNA-repair in tumor cells.

ABSTRACT

Rett syndrome (RTT) is a rare, neurodevelopmental genetic disorder that develops in early childhood and influences many functions within neurobehavioural domains. The core of phenotype symptoms includes severe linguistic and motor impairments. The onset of RTT is characterised by a gradual or sudden loss of speech and hand function followed by a slow decrease in acquired gross motor skills with subsequent severe functional dependence. RTT is associated primarily with mutations in MECP2, a gene located on the long arm of the X chromosome (Xq28). The severity of impairments depends not only on genotype, but on the extent of X inactivation. However, CDKL5 and FOXP1 gene mutations have been also identified in girls affected by atypical RTT.

Despite sharing neurological features, subjects with RTT present considerable clinical variability. Research on effects of genotype of RTT is expanding in many directions. The current chapter, will discuss the correlations between genotype and motor abilities in subjects with RTT.

The main aim of this chapter is to relate functional outcomes, in particular motor impairments, to mutation type in patients with RTT. This chapter begins with a theoretical overview on genetic alterations in RTT and then focuses on motor specific impairments.

* Corresponding Author's Email: rafabio@unime.it (Tel: +39090344831).

In the second part of this chapter, we propose a preliminary research which analyzes the correlation between motor phenotype and specific genotype.

1. GENERAL INTRODUCTION

Establishing the genotype–phenotype correlations is a central goal in order to acquire a deeper understanding of genetic disorders. Studies on Rett Syndrome (RTT) are analyzing how abnormalities in specific genes can cause disease in motor abilities. Consequently, the main aim of the present study is to correlate the specific genotype mutation with different parameters of motor impairment. In the first paragraph, entitled “Genetics and Clinical Features of RTT”, we consider new findings in the genetics field related to RTT. In the second paragraph, entitled “Motor features in RTT”, we discuss motor specific impairments in RTT. In the third paragraph, we present a study in which a large sample (195 girls with RTT) with specific motor disability (in walking, use of hands, problems related to the feet and scoliosis) is analyzed in relationship with their specific genotype.

1.1. Genetics and Clinical Features of RTT

RTT is an X-linked genetic disorder affecting almost exclusively females. It is caused by mutations in the gene encoding the methyl CpG binding protein 2 (MECP2) (Hagberg, Aicardi, & Ramos, 1983; Amir, Van den Bellver, Wan, Tran, Francke, & Zoghbi, 1999). Clinical features of classical RTT include a characteristic developmental regression involving impairment of mobility and loss of learnt speech and skilled intentional hand movements, accompanied by stereotypic hand movement automatisms (Ross et al., 2016). Associated features, such as microcephaly, respiratory/autonomic abnormalities, seizures, growth deficits and early hypotonia are highly present (Neul et al., 2010; Fabio et al., 2014; 2016).

The course of this syndrome is divided into four characteristic stages. After an apparent normal development during infancy, the girls with RTT go through a period of developmental regression (Fabio, Antonietti, Marchetti, & Castelli, 2009a; 2009b). Once developmental regression begins, the individuals with RTT usually progress through four stages: early onset deceleration stage, rapid destructive stage, pseudostationary stage, and motor deterioration stage. After the regression most children are unable to walk, talk, or use their hands for functional activities, but there is considerable variability in this regression, mainly determined by genotype (Sigafos, Green, Schlosser, O’Eilly, Lancioni, Rispoli, et al., 2009). The girls who have some, but not all of the necessary criteria to be diagnosed with RTT, are categorized as atypical or as variant forms (Hagberg & Witt-Engerström, 1986).

The term ‘variant’ was coined to describe an onset of Rett like phenotypes that deviate from the classical clinical presentation of this syndrome (Leonard, Cobb & Downs, 2017). These phenotypes included: fruste forms, congenital variant (mostly caused by mutations in FOXG1; Ariani et al., 2008) early seizure variant (mainly caused by mutation in cyclin-dependent kinase-like 5 (CDLK5; Fehr, 2013), male, late childhood, regression and preserved speech variant (mostly associated with Arg133Cys mutation; Urbanowicz, Downs, Girdler, Ciccone & Leonard, 2015) or a C-terminal deletion (Zappella, 1992; De Bona et al., 2000).

The fruste form presents a later age of onset compared with the classical form, with regression occurring between 1 to 3 years of age, hand use is sometimes preserved with minimal stereotypic movements (Chahrouh1 & Zoghbi, 2007). The preserved speech variant is characterized by the ability to speak a few words, although not necessarily in context, and by normal head size (Zappella et al., 2001). The congenital form, the more severe variant, is characterized by the lack of the early period of normal development. Another severe variant is a form of classical RTT with onset of seizures before the age of 6 months, and was associated with mutations in CDKL5 (Ariani et al., 2008; Evans, Archer, Colley, Ravn, Nielsen, Kerr, et al., 2005; Larsson, 2013; Pini, Bigoni, Engerström, Calabrese, Felloni, Scusa et al., 2012; Rajaei, Erlandson, Kyllerman, Albage, Lundstrom, & Karrstedt et al., 2011).

Considering the heterogeneity of RTT, it is important to investigate and establish the genotype-phenotype correlations in order to obtain a clear clinical picture of RTT.

1.2. MECP2 Mutations and Functions

In 1999, a mutation was found on the gene MECP2 locus Xq28, which represent the main underlying cause of RTT (Amir et al., 1999). In fact, in the majority of cases RTT is caused by de novo mutations in the MECP2 gene. This gene is a transcriptional repressor involved in chromatin remodeling and the modulation of RNA splicing (Chahrouh, & Zoghbi, 2007). It encodes methyl-CpG binding protein 2 (Amir, Van den Bellver, Wan, Tran, Francke, & Zoghbi, 1999), an abundant nuclear protein that is considered to be important in chromatin-level regulation of transcription (Lyst & Bird, 2015).

Moreover, MeCP2 mediates transcriptional inhibition by binding to methylated CpG and CpA dinucleotides in the genome (Guo et al., 2014; Gabel et al., 2015) and recruiting co-repressor complexes (Nan, 1998; Kokura, 2001). MeCP2 may also function as an activator of transcription (Li et al., 2013) amongst other functions (Lyst & Bird, 2015).

MECP2 comprises of four exons that code for two different isoforms of the protein, due to alternative splicing of exon 2. The more abundant MeCP2-e1 isoform contains 24 amino acids encoded by exon 1 and lacks the 9 amino acids encoded by exon 2. The start site for the MeCP2-e2 isoform is in exon 2 (Chahrouh1 & Zoghbi, 2007; Dragich et al., 2007; Kriaucionis and Bird, 2004; Mnatzakanian et al., 2004).

MeCP2 is essential for normal brain function. Aberrations in this gene result in a subset of the commonly observed symptoms of RTT. Precisely, the loss of MeCP2 disrupts the given brain region or system from which it is deleted. Deletion from GABAergic circuits produces a near-complete Mecp2-null phenotype, including motor and cognitive impairments (Chao et al., 2010). Postnatal deletion of Mecp2 causes RTT-like phenotypes (Cheval et al., 2012).

It is possible to conclude that disruptions in MECP2 are the main cause of classic and variant forms of RTT. However, MeCP2 depletion studies have revealed that MeCP2 mutations are associated with other neuropsychiatric disorders, such as learning disabilities, autism spectrum disorders (Carney et al., 2003; Lam et al., 2000), bipolar disease (Klauck et al., 2002) and juvenile-onset schizophrenia (Cohen et al., 2002). In addition, mutations in MECP2 gene can also cause severe mental retardation with epilepsy and Angelman-like syndrome in females (Milani et al., 2005; Watson et al., 2001).

Given this genetic and clinical variability, the need for genotype-phenotype studies is a great opportunity for new discoveries.

1.3. CDKL5 and FOXG1 Gene Mutations

In literature, MECP2, CDKL5, and FOXG1 have been reported to be the causative genes of RTT. Mutations in the CDKL5 gene were often associated with a rare congenital disorder, characterized by intractable early-onset seizures and RTT-like features (Chahrour1 & Zoghbi, 2007). However, FOXG1 mutations are the rarest and least studied. According to the FOXG1 variant database of the International Rett Syndrome Foundation only 20 pathogenic variants have been found to date (Christodoulou, Grimm, Maher, & Bennetts, 2003; Christine, Lee, Lim, Kim, Hwang & Chae, 2015).

Kortum and colleagues (2011) have delineated the phenotype of FOXG1 mutation in positive patients. The FOXG1 phenotype is characterized by severe mental retardation, hypotonia, absent language, postnatal microcephaly, dyskinesia, corpus callosum hypogenesis, developmental epilepsy, mental retardation, and severe speech impairment (Christine, Lee, Lim, Kim, Hwang & Chae, 2015; Kortum et al., 2011; Philippe et al., 2010). This phenotype is called congenital variant of RTT. Although, many features of patients with FOXG1 mutation are similar to RTT, other clinical features differ from the classical presentation of RTT. For example, the presence of dyskinesias and brain imaging abnormalities, as well as the lack of regression and lack of respiratory arrhythmia (Kortum et al., 2011). Based on this onset of symptoms and the combination of developmental and brain imaging features observed in individuals with FOXG1 mutations, Kortum and colleagues (2011) have argued that it is possible to identify the FOXG1 phenotype as a FOXG1 syndrome and not as a RTT variant.

1.4. Severity and Genotype-Phenotype Relationships

The MECP2 mutation is related to clinical severity and influences many aspects of the phenotype. The severity of impairments depends not only on genotype, but on the extent of X inactivation. Phenotype-genotype correlation studies have shown that the most severe mutations are associated with Arg270X, Arg255X and Arg168X, whereas Arg133Cys, Arg294X and C-terminal deletions are associated with less-severe phenotypes (Leonard, Cobb & Downs, 2017). Precisely, the girls with severe mutations are less able to walk, retain hand use or use words, and tend to be diagnosed at an earlier age (Fehr, 2011). Whereas individuals with C-terminal deletions show later loss of skills and onset of stereotypies (Bebbington et al. 2010). Moreover, it has been found that R133C mutation causes a milder phenotype (Kerr et al., 2006; Leonard et al., 2003; Neul et al., 2007), whereas the R270X mutation is related to increased mortality (Bienvenu & Chelly, 2006).

2. MOTOR FEATURES IN RETT SYNDROME

As reported previously RTT is a disorder that causes a neurological and developmental arrest which manifests itself in a variety of disabilities, such as loss of functional hand use, loss of acquired speech, apraxia, ataxia, autonomic system dysfunction, epilepsy, breathing abnormalities, failure to thrive and muscle tone irregularities (Hagberg, 1993; Lotan, 2006; Kerr, & Julu, 1999). With regard to motor abilities, patient present alterations in the motor

system that are observed in the first months of life (Einspieler, Kerr, & Prechtl, 2005; Nomura, & Segawa, 1990); despite the fact that some girls gain the ability to walk, eventually they suffer from a motor deterioration that impairs gait, mobility and balance and compromises both upper and lower extremities.

2.1. Motor Characteristics According to Rett Syndrome Stages

Seen as the symptoms follow a certain course, the syndrome is described as divided into stages. Some of these overlap, and in some cases they do not present classic signs that fulfill the necessary criteria, therefore are classified as atypical (Trevathan, 1989). In later revisions one of the main aspects that has been excluded is the “sudden” onset of the pathology (Hagberg, 1993; Hagberg, & Witt Engerstrom, 1986); indeed the regression is not always clearly visible, and may be more subtle and gradual (Fehr et al., 2011; Jackowski et al., 2011; Lotan, 2006). Many revisions of the clinical criteria have been made in the last decade, allowing a clarification of the “variant” forms, such as the “early seizure onset variant” (CDKL5 disorder; Fehr, et al. 2013) and the the *Zappella* or preserved speech variant (Zappella, 1992).

Despite the fact that the classification of the stages is not as restrictive as before, there are common features, especially with regard to how motor skills are affected; this section will summarize the characteristic of each phase with particular emphasis on the motor abilities.

Stage I: Onset. Most children at this stage are not yet diagnosed as having RTT; it begins around the age of six to eighteen months, and most often, patients are diagnosed as having hypotonia, cerebral palsy, autism or both (Leonard, Bower & English, 1997). The child will display a slow rate of motor development, and may exhibit attempts at walking, but, because of the flaccid muscle tone, many don't reach this major milestone.

Stage II: The rapid destructive phase. The regression and the loss of acquired developmental milestones is the significant characteristic of stage II. The child (around one to three years old) may still not be diagnosed as having RTT or a final diagnosis may still be pending. The symptoms of this stage can include seizures, deceleration of head growth, irregular breathing or hyperventilation and initiation of spinal asymmetry. The main characteristic of this phase is the loss of purposeful hand use, which is replaced by the stereotypic hand movements.

Stage III: Pseudo-stationary stage. Is characterized by a relatively calm period, nevertheless, during this stage, most of the individuals with RTT develop significant problems, such as deformities and contractures (Larsson, & Engerstrom, 2001). The difficulty in motor planning is affected by ataxia and apraxia, and deambulation is limited because of spasticity and scoliosis.

Stage IV: Late motor deterioration. Significant decrease and lack of mobility is characteristic of stage IV. Many of the individuals with RTT, although non-ambulatory, may still be able to participate in a supported transfer (e.g., moving from a wheel-chair to a bed). Individuals who constantly use a wheel-chair will typically present a worse phenotypic expression, consequentially requiring more care. In some cases, however, additional medical issues are encountered. Such problems may include worsening scoliosis and contractures, lower extremity atrophic changes (Lotan, 2006), and growth retardation will usually be more apparent

(Motil, Schultz, Wong & Glaze, 1998). Often patients may present Parkinsonian features (Hagberg, 2005; Roze et al., 2007).

2.2. Neurological and Muscle Symptoms

Since the early description of RTT, it was clear that it referred to neurodevelopmental disorders and not a progressive encephalopathy (Larsson, 2013). The atrophy or the reduced dendritic/synaptic development causes the brain to be smaller. Studies which refer specially to the motor abilities have found a link between the reduction in size of the cerebellum and motor deficits in RTT. For example, in studies carried out on modified mice including *Mecp2*-knockout lines with early motor problems, major deterioration was found especially in the motor control regions, e.g., prefrontal and motor areas, with the involvement of noradrenergic and serotonergic systems (Santos, et al., 2010). Julu et al. (2008) have associated most of the clinical aspects of the syndrome with an immature brain, and some of these present an extra-pyramidal origin.

Different neurological features may impact motor function, in particular hypotonia and weakness in the early years and dystonia and bradykinesia in the later years (Hagberg, 2002). Fehr et al. (2011) have found that in the early stages of the syndrome, patients may learn to sit and walk, but the subsequent alteration of the muscle tone (e.g., bradykinesia) influences the retention of upright posture, and impedes deambulation. Difficulties in the motor coordination and the confusion reported concerning RTT patients, is due to the ataxia and gait apraxia (Larsson, 2013). These symptoms encumber the production of what we perceive as the simplest actions, such as sitting down or lowering from kneeling to heel sitting. As with other characteristics of RTT, variability among individuals is the norm. The infant with RTT will typically show hypotonia or the muscle tone might be within the low margin of the norm. With age, most individuals with RTT change from being hypotonic to becoming hypertonic (mostly rigidity, usually starting from lower extremities). 30% of adults with RTT remain hypotonic, 40% show rigidity as their main tonal characteristic and 30% become dystonic (Kerr, 1992). These changes influence the handling of the child and therefore necessitate ongoing evaluation of muscle tone by the therapist.

When muscle tone of the individual with RTT gradually changes from low to high, the change might cause a unique phenomenon. In contrast to children with cerebral palsy (toe walking), the child with RTT might present an asymmetrical reaction, causing her to side-tilt the trunk, leading to initial development of asymmetry of the spine, eventually resulting in scoliosis (Figure 1). Another unique reaction of individuals with RTT to the shortening of the Achilles tendon could be the tilting of the pelvis backwards, causing the child to lose the ability to walk independently. When an appropriate foresight planning is performed, such events should be expected and might be dealt with in order to prevent their severe consequences.

As has been mentioned above, because of the abnormal muscle coordination and the neurological impairment, individuals with RTT stiffen in time and the presence of muscle spasms increase the possibility of developing deformities, such as scoliosis. It seems that earlier onset is present in the more severe mutations, such as Arg255X, and the progression is worse in patients who are unable to walk. The presence of deformities (e.g., Figure 2) has been noted since the early studies which reported as a common feature the presence of asymmetry on the right side (Cass et al., 2003; Hagberg, & Romell, 2002). One of the major problems of scoliosis

is that is usually progressive; the prognosis of scoliosis development in RTT is worse, when the scoliosis appears before age five, when severe hypotonia exists from childhood, when there is an inability to walk or when walking was gained but lost at an early age (Hagberg, 1993). Scoliosis and kyphosis often begin with muscle tone problems, which are brought on by the child's inability to correctly process her body scheme (misinterpretation of proprioceptive input by the brain). Active exercise and passive range of movement routines are helpful.

Figure 1. X-ray taken in a suspended position showing scoliosis (Lotan, Merrick, & Carmeli, 2005).

Figure 2. Feet deformities (Lotan, 2006).

Recent studies on RTT mouse models, have allowed to pinpoint genotyping differentiation of specific motor impairments. For example patients with mutation p.R270X or p.R168X present a much more severe phenotype, while those with p.R133C, p.R294X, and C-terminal deletions are more likely to preserve walking abilities (Bebbington et al., 2008; Neul et al., 2008). A recent study that had the aim of validating a gross motor scale, outlined a relationship between the severity of the syndrome and the gross motor abilities, in particular found that milder phenotype (e.g., p.Arg133Cys, p.Arg294 or p.Arg306Cys) showed better performances in abilities such as sitting and walking, whereas mutations such as the p.Arg270 present greater impairment (Downs, et al., 2016).

As outlined above it is important to study more in depth those abilities and the precise genetic factors that can influence them. Consequently, the aim of the present study is to correlate the specific genotype mutation with different parameters of motor impairment. In this study a large sample (195 girls with RTT) with specific motor disability (in walking, use of hands, problems related to the feet and scoliosis) were analyzed in relationship with their specific genotype.

3. METHODS

3.1. Participants

190 girls with a diagnosis of RS, ranging from age 4 to 31 (mean = 18,34 years, SD = 5,36), took part in the experiment. Their families had been contacted by the Italian Rett Association which asked them to participate in the study. All of the participants have been diagnosed with RTT following the guidelines established by the Criteria Work Group and mutation analysis of the methyl-CpG binding protein 2 gene (Table 1).

A general assessment was carried out by a psychologist through the Vineland Adaptive Behavior Scale (VABS) (Sparrow, Balla, & Cicchetti, 1984) and the standardized test Rett Assessment Rating Scale (RARS, Fabio et al., 2005; Vignoli et al., 2010).

3.2. Material

Functional scales. The Vineland Adaptive Behavior Scales is used for diagnosis of intellectual and developmental disabilities. The Scales are organized in four domains: Communication (Receptive, Expressive, Written); Daily Living (Personal, Domestic, Community); Socialization (Interpersonal Relationships, Play and Leisure Time, Coping Skills); and Motor Skills (Gross, Fine).

The Rett Assessment Rating Scale (RARS) is a standardized scale used to evaluate subjects with Rett syndrome (Fabio, Martinazzoli & Antonietti, 2005). It is constructed following the diagnostic criteria for RTT proposed by DSM-IV-TR (APA, 2010) and recent research and clinical experience. It follows a structure similar to that used for the diagnosis of the pervasive developmental disorders included in the same nosographical category as RTT (i.e., Childhood Autism Rating Scale, CARS).

Unknown or not specified	90
Total	195

A total of 31 items was generated as representative of the profile of RTT. Each item concerns a specific phenotypic characteristic and describes four increasing levels of severity. Each item is provided with a brief glossary explaining its meaning in a few words. Each item is rated on a 4-point scale, where 1 = within normal limits, 2 = infrequent or low abnormality, 3 = frequent or medium- high abnormality, and 4 = strong abnormality. Intermediate ratings are possible; for example, an answer between 2 to 3 points is rated as 2.5. For each item, the evaluator circles the number corresponding to the best description of the patient. After a patient

has been rated on all 31 items, a Total score is computed by summing the individual ratings. This Total score allows the evaluator to identify the level of severity of RTT, conceptualized as a continuum ranging from mild symptoms to heavy deficits.

3.2.1. Motor Scale

The Motor subscale of the RARS was obtained by summing up each of the four items. The items considered are walking, use of hands, scoliosis and problems related to feet. Below the precise scale for each item is presented.

X. Walking

1	1.5	2	2.5	3	3.5	4
The girl is able to maintain an erect position and to walk by herself. She knows how to look where she is going, walk on any surface and go up and down stairs.		The girl is able to maintain an erect position but sometimes needs support when walking.		The girl is able to maintain an erect position but always needs support when walking.		The girl is unable to maintain an erect position or walk by herself. She needs a wheelchair or a pram in order to move around.

XI. Hands:

1	1.5	2	2.5	3	3.5	4
Functional use of the hands is only slightly affected; the girl manages to grip and hold objects for long enough to enable her to make ample movements. She has good hand-eye coordination. Stereotypes do not influence the intentional use of the hands.		Functional use of the hands is more compromised; the girl manages to touch, push or hit objects but not to grip them. Hand-eye coordination is scarce. The girl is inhibited in moving by stereotypes.		Functional use of the hands is compromised; the girl is not always able to use her hands intentionally; she does not always manage to touch objects, even if strongly motivated to do so, especially in the presence of marked stereotypes.		Functional use of the hands is almost completely compromised; the girl is not able to use her hands intentionally; she does not manage to touch objects even if strongly motivated to do so, especially because of insistent stereotypes.

XII. Scoliosis:

1	1.5	2	2.5	3	3.5	4
The girl shows no signs of scoliosis.		The girl shows signs of minor scoliosis.		The girl shows signs of major scoliosis.		The girl shows signs of very serious scoliosis.

XIII. Feet:

1	1.5	2	2.5	3	3.5	4
The girl has no problems with her feet.		The girl has slightly small feet, with minor circulation problems.		The girl has small, valgus or different sized feet, with circulation problems.		The girl has problems with her feet, to the extent that she is unable to walk.

3.3. Results

Results are presented in relation to the general motor subscale of the RARS and the specific scale of walking, use of hands, scoliosis and problems related to the feet.

With reference to the first analysis, to calculate the general motor subscale of the RARS, the sum of each type of motor item was analyzed. With reference to the second analysis, the four parameters of the motor scale were used.

Figure 3. Genomic structure of MECP2 gene and localization of general motor in the coding regions.

To proceed with the genotype-phenotype correlation, the general motor scale score was divided into three categories namely low, medium and high level of severity on the basis of the 33rd and 66th and 100th percentiles for the variable. Based on low, medium and high level of severity, participants were placed within one of the three types of categories. Because some of the girls with RTT show only clinical features and not mutation in MECP2, only 105 patients were included in the analysis (Table 1).

As shown in Figure 3 and 8, patients with a truncating mutation after NLS manifested a lower degree of impairment on general motor scale than patients with a truncating mutation within NLS $\chi^2 = 5.74$, $p < .03$.

With reference to the second analysis, the genotype-phenotype correlation was carried out with the four parameters of the general motor scale: walking, use of hands, scoliosis and problems related to the feet. To calculate these correlations, the walking scale score was divided into three categories namely low, medium and high level of severity on the basis of the 33rd and 66th and 100th percentiles for each variable. Based on low, medium and high level on high levels of severity, participants were placed within one of the three types of categories.

As shown in Figure 4 and 9, patients with a truncating mutation after NLS manifested a lower degree of impairment on walking scores than patients with a truncating mutation within NLS $\chi^2 = 3.11$, $p < .05$.

To further calculate these correlations, the use of hands score was divided into three categories namely low, medium and high level of severity on the basis of the 33rd and 66th and 100th percentiles for each variable. Based on low, medium and high levels of severity, participants were placed within one of the three categories.

Figure 4. Genomic structure of MECP2 gene and localization of use of walking produced in the coding regions.

As shown Figure 8, patients with a truncating mutation after NLS manifested a lower degree of impairment on general motor scale than patients with a truncating mutation within NLS $\chi^2 = 0.74$, $p < .44$.

Furthermore the scoliosis score was divided into three categories namely low, medium and high level of severity on the basis of the 33rd and 66th and 100th percentiles for each variable. Based on low, medium and high levels of severity, participants were placed within one of the three categories.

As shown in Figure 6, patients with a truncating mutation after NLS manifested the same degree of impairment on scoliosis than patients with a truncating mutation within NLS $\chi^2 = 1.74$, $p < .23$.

Finally the feet problem score was divided into three categories namely low, medium and high level of severity on the basis of the 33rd and 66th and 100th percentiles for each variable. Based on low, medium and high levels of severity, participants were placed within one of the three categories.

As shown in Figure 7 and 10, patients with a truncating mutation after NLS manifested a lower degree of impairment on the feet problem score than patients with a truncating mutation within NLS $\chi^2 = 3.74$, $p < .05$.

Based on the same categories above presented (low, medium and high levels of severity) participants within the most numerous genotypes of our sample were placed in each precise genotype. Figure 11 shows their precise level of impairment. From these data patients with R168, R255 and R270 show the most serious impairments.

CONCLUSION

In this study, disease-causing mutations have been related to the intensity of the parameters of the motor impairments measured by the subscale of the RARS (Antonietti et al., 2007) namely the general motor scale, the walking subscale, the use of hands subscale, the scoliosis subscale and the feet problems scale. Comparisons between the truncating mutations differently affecting functional domains support the idea that the crucial factor that leads to different phenotypes is the integrity of NLS.

As in the study of Fabio et al. (2014) and Falzone et al. (2015) we suppose that if the protein can penetrate into the nucleus and link to Methylated CpG, it maintains a residual role causing a milder clinical damage.

The two mutations produced differential phenotypic effects in the five domains here analyzed. Our data confirms the preexisting literature (e.g., Bebbington et al., 2008; Downs, et al., 2016; Neul et al., 2008), in particular genotype-phenotype correlation showed that patients with p.R270X, p.R255X or p.R168X present a much more severe phenotype in terms of specific motor impairment, in particular for walking and problems related to the feet, whilst patients with R306 present a medium level of impairment, confirming earlier classifications (medium-high level of impairment; Fabio et al., 2014). Those with p.R133C and p.R294X show milder motor deterioration. Many studies have associated scoliosis to the more severe mutations (e.g., Arg255X; Leonard, Cobb, & Downs, 2016), while in the present study there were not significant differences between patients with a truncating mutation after NLS or within NLS.

The most important innovation introduced in the study was the use of the correlation between motor scale in relation to the specific genotype.

ABSTRACT

Fragile X syndrome (FXS) is the most common inherited cause of intellectual disability. However, findings reported in cross-sectional studies on this population are heterogeneous. This chapter focuses on the longitudinal assessment of a boy with FXS from 12 months through to 6 years of age using two tests: one that assesses psychomotor development and another that assesses neuropsychological maturity. The child had attended an Early Childhood Development Intervention Center-ECDIC since 12 months old. He was administered the *Brunet-Lézine Revised Scale of Psychomotor Development in Early Childhood* until 36 months and underwent CUMANIN neuropsychological testing from age 3 to 6. The results obtained allow us to observe trends in the boy's psychomotor development and neuropsychological maturity over time. Significant commonalities between these results and those of previous cross-sectional studies are discussed. Furthermore, some conclusions are drawn that may prove valuable to professionals and researchers interested in this syndrome.

1. INTRODUCTION

Fragile X syndrome (FXS) is the leading known inherited cause of intellectual disability in the world and the second most common chromosomal abnormality after Down syndrome, affecting approximately 1 per 2,633 males and 1 per 4,000 females (Kidd et al., 2014; Fernández-Carvajal et al., 2009). Given that this is a disorder linked to the X chromosome, it mostly affects males, while females are carriers (Bailey, Hatton, Tassone, Skinner & Taylor, 2001; Wilding, Cornish & Munir, 2002). Fragile X syndrome is an X-linked monogenic disease caused by a mutation in the FMR-1 gene located at Xq27.3 (Bagni, Tassone, Neri & Hagerman, 2012).

The behavioral phenotype presents itself in a myriad of ways among this population (Verkerk et al., 1991). However, it has been observed that FXS involves cognitive functioning that suggests a common profile in this group of people. According to Brun-Gasca (2006), we can find general characteristics that do not appear in every affected person, and which may vary depending on sex and mutation type. Specifically, clear sex-dependent differences are found (Murphy & Abbeduto, 2007). Cognitive deficits are therefore less evident in girls than in boys; between 30 and 50% of females with a full mutation have intellectual disability ranging from mild to moderate, whereas only a small number have severe disability. One-third of females display normal intelligence and, in some cases, learning disorders (especially in mathematics) as well as social and relationship problems. Combined with less noticeable effects in terms of physical features, all this makes an early diagnosis of this syndrome in girls difficult. Regarding the mutation type in boys with permutation, the phenotype is very similar to that of boys with full mutation (Cornish et al., 2008).

Given these sex-related differences, the data discussed herein refer to boys with FXS. Regarding linguistic abilities, the majority of studies have focused on language expression deficits, while studies examining language reception have yielded conflicting results (Abbeduto et al., 2003; Abbeduto, Brady & Kover, 2007). Fürgang (2001) found vocabulary level to be the least affected by auditory processing problems and a delay in syntactic development. However, Brun-Gasca and Artigas-Pallarés (2001) hold the view that those with FXS grasp syntax with relative ease. Children with FXS also present language deficits when it comes to organizing and sequencing information, exhibiting perseveration, echolalia, and poor communication skills. Therefore, they struggle to know when it's their turn to speak and maintain eye contact with the speaker; they also find it difficult to keep up with the topic of conversation. What is more, the use of tangential language frequently occurs. Typical behavior in individuals with FXS, namely avoiding eye contact, usually surfaces when speech development begins and not at earlier stages (Van der Molen et al., 2010). FXS also affects oral-motor functions (e.g., low muscle tone, dyspraxia, intelligibility problems) as well as voice problems (Fürgang, 2001).

Intellectual functioning heterogeneity is highly characteristic of this syndrome, which speaks to the importance of conducting a proper individual evaluation of all areas involved (Abbeduto et al., 2007; Van der Molen et al., 2010). In fact, some features frequently reported in males with FXS include ongoing deficits in short-term memory (Munir, Cornish & Wilding, 2000a); visual spatial memory (Munir et al., 2000a); executive function (Hooper et al., 2008; Munir, Cornish & Wilding, 2000b; Scerif, Cornish, Wilding, Driver & Karmiloff-Smith, 2007); and difficulties in processing sequential and abstract information (Van der Molen et al., 2010).

Males with FXS are usually shy and socially anxious; they avoid eye contact or do so selectively, more often addressing people they know rather than people they don't know (Lewis et al., 2006). They do not avoid social situations at an early age, quite the opposite in fact: they usually seek them out and expose themselves to these scenarios (Robles-Bello & Sánchez-Teruel, 2013a).

As can be observed, there is a significant body of scientific literature on FXS. However, the majority of studies have applied cross-sectional methodologies, meaning that outcomes based on longitudinal data are limited; these could provide a more epigenetic understanding of this disorder. From this perspective, the current study proposes two specific aims: first, to obtain a full description of a boy with FXS which serves to increase knowledge about the syndrome's underlying features focusing on individual data covering a six-year period; and second, to acknowledge the importance of individualized early childhood intervention, particularly given the heterogeneity within this disorder.

2. METHOD

2.1. Subject

X is a boy born in January 2008 who was referred to an Early Childhood Development Intervention Center-ECDIC) (*Centro de Desarrollo Infantil y Atención Temprana-CDIAT*) (Robles-Bello & Sánchez-Teruel, 2013b) with a pediatric diagnosis of psychomotor delay and communication disorder with hyperactivity, plus a potential diagnosis of FXS taking into account phenotypic and neuropsychological traits. This diagnosis was later confirmed, further indicating that X was a carrier of a full mutation with an expansion of 250 CGG triple repeats (PCR to amplify the region where CGG expansion of the FMR-1 gene occurs—at the FRAXA locus—and capillary electrophoresis).

2.2. Measures

Testing instruments varied over the course of the evaluation process on the basis of the child's chronological age. The measures used are described below.

Brunet-Lézine Revised Scale of Psychomotor Development in Early Childhood (Josse, 1997; n.d.). This scale applies to toddlers and infants aged 0 to 30 months and aims to measure the child's maturity level in the four areas under examination: postural-motor control; hand-eye coordination (cognition-perception); language/communication; and sociability/autonomy. It allows us to obtain a development age and an overall development quotient for the child, as well as a partial assessment of the child's development age and development quotient, for each of the aforementioned areas. The measure has adequate reliability (stability coefficients—test/retest at 15-day intervals in infant samples at ages 6, 12 and 18 months—of 0.70 and higher; there is also item homogeneity, reporting Cronbach's alpha of between 0.69 and 0.87). Internal validity of the different scales in relation to the general scale ranged from 0.49 to 0.67 (Ramos-Martín, Sancho-García, Cachero-Sanz, Vara-Arias & Iturria-Matamala, 2009).

The *Child Neuropsychological Maturity Questionnaire-CUMANIN* (Portellano, Mateos & Martínez, 2000) is an individually administered test that assesses neuropsychological maturity in children aged between 3 and 6 years (36 months to 78 months). The questionnaire takes between 30 and 50 minutes to complete. The CUMANIN comprises main scales (psychomotricity, language articulation, language expression, language comprehension, spatial structuring, visual perception, iconic memory and rhythm) and subscales (attention, verbal fluency, reading, writing and laterality). The Cronbach's alpha reliability level varied from scale to scale, reporting 0.71 (psychomotricity), 0.92 (language articulation), 0.73 (language expression), 0.72 (language comprehension), 0.81 (spatial structuring), 0.91 (visual perception), 0.57 (iconic memory) and 0.72 (rhythm).

2.3. Procedure

The evaluation process took place at the start and end of each age period (1, 2, 3, 4, 5 and 6 years). The results obtained allow us to observe trends in the child's development over time. He was administered the *Brunet-Lézine Revised Scale of Psychomotor Development in Early Childhood* (Josse, 1997; n.d.) until 36 months and took the CUMANIN neuropsychological test from age 3 through 6. Throughout the entire evaluation process, X regularly attended daycare (in the first three years) and later school. Furthermore, X was enrolled in an early intervention program for the first three years of his life under Public Health Law (Consejería de Salud, 2017).

The principal aim of "Early Childhood Intervention" is to promote a child's well-being and family development by enabling boys and girls with developmental disorders—or those at risk for exhibiting them—to achieve fuller integration within family, school and social life (Candel, 2005). This early child intervention from birth up until age 6 focuses, among other things, on enhancing cognitive performance, autonomy, language and communication, and motor skills at an Early Childhood Development Intervention Center-ECDIC. In some European countries, Spain included, the process begins at birth and is carried through until 6 years of age (until 3 in some autonomous regions of Spain). It is also free to users and co-funded by the national public healthcare system (Robles-Bello & Sánchez-Teruel, 2013).

The direct work sessions with X lasted 45 minutes, with the boy attending the ECDIC three times a week. The interdisciplinary team made up of physiotherapists, speech therapists and psychologists, in collaboration with the parents, adjusted the program to meet the needs of the child and his family. These work objectives were fulfilled using the program developed by Zulueta, Mollá, Martínez, Lago de Lanzos and Arrieta (2004). The family's session attendance rate was 100%.

3. RESULTS

The results shown in Table 1 below correspond to the evaluation period spanning 3 to 6 years using the CUMANIN test, reflecting the raw and centile scores for each evaluated area.

Figure 1. Development level attained on the Brunet-Lézine scale before and after each treatment year up until 30 months.

Table 1. Raw and centile scores on the Child Neuropsychological Maturity Questionnaire (CUMANIN)

4. DISCUSSION

This study focused on the developmental period spanning 12 months to 6 years of a boy diagnosed with fragile X syndrome. Overall, the development of X shows a trend to improvement during the first three years of his life; however, this does not continue in the same way from age 3 onwards. Functional impairment is more pronounced in the last three years. His neuropsychological profile is characterized by peaks and dips in learning, with language being the area where most progress is made and autonomy the most representative in the first three years. Although this child's trajectory cannot be generalized, his follow-up data do not coincide with findings reported in cross-sectional studies (Roberts, Hatton & Bailey, 2001).

Following the first year of intervention, family and daycare subjectively perceive a positive trend in X's acquisitions. This assessment holds true in subsequent regular contact sessions. The raw scores obtained using the psychomotor development test (Josse, 1997) confirm this trend across the different assessed areas (motor, cognitive, language and autonomy).

Within the context of this positive progression profile, we sought to identify whether acquisition increase between years 0 and 3 maintained a similar rate of growth. The gains in raw scores for each period suggest positive growth in motor and language acquisition skills. Regarding language, similar gains are observed in scores across each period, whereas age 3 is seen as a stage of significant gains in motor acquisition. These results are not consistent with those obtained by Roberts et al., (2001), who identified language as the area where least progress is made, possibly due to the working memory problems discussed in some previous studies (Baker et al., 2011). However, growth rates in cognition and autonomy slow according to subsequent evaluations.

The following set of results correspond to the developmental period spanning 3 to 6 years, where learning is assessed using the CUMANIN test which allows for a more in-depth assessment of the different areas of development. Rice, Warren and Betz (2005) argue that language skills in children with FXS present particular challenges when it comes to the expression component, consistent with the development of nonverbal cognitive abilities. Furthermore, they report voice and speech problems that make it difficult to understand their expressions. The results obtained for X partially concur with this conclusion. When comparing the ability to repeat previously heard expressions (language expression) and speaking skills (language articulation) with nonverbal maturation (nonverbal development), his performance is comparable to what is expected between the ages of 3 and 5 and under 6. The comparison with verbal development points to a similar trend, although expression impairment is observed from age 3 onwards.

These outcomes regarding his language skills vary in terms of comprehension. In this case, the comparison made with the child's level of nonverbal and verbal maturity suggests that his ability to extract information from a previously heard story is one of the boy's strengths. His performance level across the different evaluated periods (3, 4, 5 and 6 years) is similar to that observed in a population matched on chronological age. Estigarribia et al., (2011) also found that recall of a previously heard story did not differ significantly from that of the norm group after having controlled for nonverbal development level and short-term memory. The discrepancies found between language dimensions (comprehension, expression) when comparing performance, either with verbal or nonverbal maturity level, supports the conclusion drawn by Price et al., (2008). According to these authors, the link

between cognitive and linguistic abilities (syntax expression and comprehension) in FXS cases—and possibly in other conditions such as Down syndrome—is more flexible than that observed in cases involving norm groups.

Another point of interest in this discussion is the examining of X's progress based on raw scores (Van der Molen et al., 2010). This trend in abilities is always positive across all evaluation periods, although they differ at the growth curve observed. The repeat of previously heard expressions emerges when the child approaches the end of age 4, increasing very slowly yet progressively. Growth in this ability (based on standard deviations in relation to the norm group mean) remains relatively constant. A different pattern is observed for speech production (language articulation) which develops very slowly from age 3 onwards, achieving greater gains between age 5 and 6. Despite this, the discrepancy in performance among children of a similar chronological age increases gradually with advancing age. Taking into account the raw scores, this positive trend is also observed in the child's ability to understand the elements included in a previously heard story. His capacity to comprehend is present from the age of 3, generally maintaining a positive developmental trajectory until 6 years.

Overall nonverbal development (nonverbal development) is progressive but very slow and remains at the lower functioning range between the ages of 3 and 5. Evaluations at age 6 report significant performance improvements, which are especially influenced by psychomotricity development (age 6) and ability gains in iconic memory (age 5). However, auditory memory ability, measured through rhythm, maintains a low profile across the different evaluation stages.

The visual perception task involves copying geometric shapes and is defined by Van der Molen (2010) as a performance measure using abstract items. For this researcher, performance in FXS cases is poor (e.g., lower than expected for nonverbal development level) on tasks that contain abstract items as opposed to tasks that contain concrete items, that is, visual perception skills and better processing of meaningful information. X's visual perception performance does not completely follow the pattern suggested by Van der Molen (2010). The discrepancy between task functioning and the child's level of nonverbal maturity is noticeable at age 6; however, this performance—from approaching the end of age 3 up until 4 and 5 years—assumes values close to what might be expected, albeit inconsistently. In terms of the trend in raw scores, X's ability to copy shapes arises at age 3 and holds stable until age 5. His performance improves at this age, yielding a significant 5-point gain. He makes favorable progress in year 6, achieving scores close to those obtained by the norm group mean. Despite this, the growth rate at age 6 is slower than at age 5.

Spatial organization ability (spatial structuring) is found to be in line with the level of nonverbal maturity across all evaluated periods; it is even slightly above expectations at age 5. The trend in raw scores across all age groups is continual and positive, yielding an improvement in centile position, especially from the end of age 4 to the end of age 6, a period in which performance level is similar to that found in the norm group. This good performance may be linked to the spatial structuring task features covered in the CUMANIN assessment test, where a large proportion of the task's items require commands to be carried out, taking into account the axis of corporal symmetry. Kogan et al., (2009) identified egocentric spatial organization as a strength that children with FXS exhibit when compared with performance on tasks where the reference axis for spatial organization is located outside the body. A salient aspect in relation to this task is a profile similar to the one observed in the visual perception task. Kogan

et al., (2009) suggested that visual perceptual ability in children with this disorder may find themselves guided more by the spatial organization of objects than by the features of these stimuli. Hence, capacity development for spatial structuring that occurs at the end of year 4 may have facilitated visual perception task performance.

Psychomotricity is measured using an implicit procedural learning task. Bussy, Charrin, Brun, Curie and Des Portes (2011) examined this type of learning in children with FXS. These researchers define procedural learning as the acquisition and storing of rules associated with motor skills. The children identified these features slowly and unconsciously, drawing on past experience. The acquisition of implicit procedural learning in children without difficulties starts early and reaches good performance levels at age 7 (Thomas & Nelson, 2001, taken from Bussy et al., 2011). The findings reported by Bussy et al., (2011) suggest that implicit procedural learning functions efficiently in FXS. In the case of X, his performance coincides with the pattern established by Bussy et al., (2011): it is efficient across all assessed age groups, falling within expectations in nonverbal maturity and even exceeding them somewhat at age 6. However, when compared with the norm group in terms of percentile position, X finds himself in the first quartile up until age 6, an age at which he performs very well and reports efficiency levels similar to those observed in the norm group. When taking into account raw scores, performance begins at age 3 and maintains positive yet slow growth up until age 6, which is when the highest growth in these scores is observed (a 3-point gain).

The two tasks covered in the evaluation of nonverbal development level are related to memory capacity, specifically (1) rhythm, an auditory memory task; and (2) iconic memory, a visual memory task featuring concrete and meaningful material. Rhythm-related performance between the ages of 3 and 5 reveals a low profile aligned with nonverbal maturity level. The discrepancy between both scores is seen at age 6, a time when X's nonverbal development improves substantially while his ability to repeat rhythmic sequences develops at a much slower rate. The difficulties reported in this auditory task contrast with performance on the visual memory (iconic memory) task. In the latter, the overall profile is one of a development level comparable to his nonverbal development between the ages of 3 and 4 and higher between years 5 and 6. Progress in terms of raw scores suggests that rhythm performance is delayed until the end of year 4 and improves at later stages albeit very slowly (the gain stands at approximately 1 point per year).

The recall of meaningful visual material begins from the end of age 3 and holds stable until age 5, the age at which substantial improvements in the number of recalled items are observed. Progress is maintained at age 6, although less growth is seen (2-point gain). When comparing X's performance data with that of a similar age norm group, a significant deficit in both abilities between the ages of 3 and 4 is observed. However, visual memory performance between the ages of 5 and 6 improves substantially, with values approaching those obtained by the norm group; meanwhile, the significant gap in auditory task performance is maintained. Hence, the difference between both types of memory coincides with the greater difficulties in auditory memory as identified by Baker, Hooper, Skinner, Hatton, Schaaf, Ornstein and Bailey (2011), although not in the persistent trend of these results during development.

Attentional control refers to the ability to choose specific stimuli to learn about, remain attentive for a long period of time, regulate and supervise (monitor) behavior and actions, and control impulses. Attentional control is one of the domains within the executive control system. The study conducted by Cornish, Cole, Longhi, Karmiloff-Smith and Scerif (2012) showed that FXS children's accuracy in an attentional control test was lower, albeit comparable, to that

observed in children (3–10 years) of a similar mental age. This good performance coincides with the pattern observed in X up until age 5. During this period, his performance somewhat exceeds the expected level, taking into account his nonverbal development when compared with the norm group mean. However, from this age onwards, a distancing in relation to this norm group emerges. In their review of attentional control capacity in control preschoolers, Anderson and Reidy (2012) suggested that accuracy in attentional control tasks improves significantly between ages 4.5 and 5. This trend in the control group may explain the differences observed in X's performance, who continues to show progress in his ability albeit more slowly. Thus, when examining the raw scores, X's performance reveals a 2-point gain at ages 3 and 4, with a growth curve increasing trend at 5 and 6 years of age (4-point gain per year).

Another test that relates to executive functioning is that of verbal fluency (Anderson & Reidy, 2012). In this task, the child has to make a meaningful sentence based on a single word. Hooper et al., (2008) identified an overall deficit when examining executive function in males with FXS, reporting major difficulties across different domains of executive function (e.g., inhibition, working memory, set-shifting and planning), with the exception of processing speed. The data corresponding to X's cognitive flexibility in verbal fluency are very poor, irrespective of the comparison criteria (norm group, verbal maturity and nonverbal maturity). In terms of raw scores, floor-level performance is seen at the end of year 4 and rises slightly at age 5 (1-point gain). The greatest development is observed at age 6 with a 4-point gain.

An important aspect to acknowledge is the performance difference between the verbal fluency and attention tasks. Both tasks are associated with the concept of executive function. However, a significant decline is observed in verbal fluency which is not identified in attention until age 6. A possible reason for this could be the use of a visual pathway in the attention task, in line with the results from Baker et al.,'s (2011) study.

One of the core objectives of any intervention aimed at improving children's cognitive abilities is to align the treatment programs with their own features, designing the tasks around their strengths and compensating for their particular difficulties; on many occasions, this also involves introducing different types of support. In this regard, it is of interest to identify the skills and gaps in two main processing areas: auditory/verbal and visual. The scientific literature that documents FXS features gives, in some instances, contradictory information about verbal and visual processing abilities in this disorder. These gaps may be associated with the difficulty in capturing the wide range of factors that exert an influence on both these principal operating areas; the study of a population undergoing a learning/acquisition process; the different reference methods used and even individual variability, to name a few of the general factors.

The progress made by children with FXS in terms of ability acquisition varies from study to study. In their literature review, Hahn, Brady, Warren and Fleming (2015) established three possible mean trajectories (overall) of adaptive behavior functioning (e.g., communication, socialization, daily routine and motor skills) characterized by (a) a decline over time; (b) progressive development up until approximately age 10 and subsequent stabilization or decline; and (c) a positive path from infancy to age 12. Their findings suggest that the development of children with FXS is not unique. Approximately half of the children develop well over the entire evaluation period (between 30 and 120 months), while the remaining half (56%) lose adaptive skills in relation to their chronological peers as well as in absolute values, that is, when taking into account the raw scores. In cases where a decline in adaptive functioning was observed, this occurred approaching approximately 7 years of age.

Although adaptive behavior has not been examined directly in this study, it can be assumed that this behavior is influenced, among other things, by children's skill sets. From this perspective, X's overall development profile would likely correspond to a progressive form of development. Given that progress monitoring stopped before the child reached 7, the age that Hahn et al., (2015) established as a potential critical point in children's development, conclusions cannot be drawn about future progress; this especially holds true when we see that no significant differences were observed in different variables among children progressing well and those experiencing ability decline. What is more, in cases where a decline occurred, Hahn et al., (2015) observed that this could be attributed to certain domains of adaptive functioning. In the case of X, areas of particular concern could be those that we have previously described as performance levels showing less favorable trends and persistent difficulties. These may be target areas for intervention and/or for developing compensatory mechanisms.

To summarize, as to be expected, X exhibited idiosyncratic functioning: it cannot be entirely extrapolated to functioning profiles extracted from groups. Despite this, convergences with common features in FXS are seen. These include language and cognitive difficulties in general terms and, more specifically, language expression difficulties, short-term memory problems, deficits in visual spatial processing and psychomotricity, as well as difficulties in tasks related to executive functioning. However, it is also possible to identify some of these more individual elements. In the case of X, there are two main ages in which his performance differs notably from this general deficit pattern. The first period is age 3, which is when X demonstrates good performance in speech production and language comprehension; attentional control capacity, even surpassing the mean norm group; and efficient visual perception levels. The early intervention program which X and his family had actively participated in almost since his birth is considered one of the most relevant factors.

The other significant stage is the period spanning ages 5 through 6. During this period, X makes very good progress in language comprehension, outstripping learning growth recorded at earlier stages. He also performs very well in psychomotricity (especially at age 6) and in iconic memory (at age 5). However, progress is less pronounced in other abilities such as visual perception and spatial structuring. Alongside persistent difficulties in language expression, verbal fluency and rhythm, we even observe a certain loss of ability when compared with the norm group and/or his nonverbal maturity level, as in the case of attentional control. Despite all this, it should be pointed out that an examination of X's raw scores reveals positive progress, although not at the rate identified in the comparison group which shows no difficulties.

Chapter 77

CORNELIA DE LANGE SYNDROME: A REVIEW

Elizabeth A. M. Frost*, MD

Icahn Medical Center at Mount Sinai,
New York, NY, US

ABSTRACT

Cornelia de Lange syndrome (CdLS), also known as Bushy syndrome, Amsterdam dwarfism and Brachmann- de Lange syndrome is a genetic multi system disorder, usually caused by spontaneous mutation. Although present from birth, it may not always be immediately diagnosed. The estimated incidence is about 1:10,000-30,000 births. Both sexes are affected. Mortality is high early in life and neurosensory, craniofacial, musculoskeletal, cardiac and gastrointestinal abnormalities are all apparent. There is no known cure and treatment is supportive, requiring a team support system.

Keywords: genetic mutation, rare disorders, respiratory failure, dwarfism, Cornelia de Lange syndrome

INTRODUCTION

Cornelia de Lange syndrome (CdLS), is a complex syndrome of multiple congenital anomalies that vary in severity. It is genetically heterogeneous and sporadic, with an estimated prevalence of 1 in 10,000 to 30,000. Winfried Robert Clemens Brachmann (1888–1969), a German physician documented the first case when he described the features and autopsy results of a 19 day old patient who had died of pneumonia in 1916 [1]. He described, mainly, characteristics of the upper limbs and wrote on the facial symptoms less specifically. Some years later, in 1933, Cornelia Catharina de Lange, a Dutch pediatrician after whom the disorder has been named documented the cases of two girls with unusual facies and mental retardation,

* Corresponding Author's Email: Elzfrost@aol.com (Clinical Professor of Anesthesia).

one 17 months and the other 6 months, admitted within weeks of each other to Emma Children's Hospital [2]. The first child had pneumonia and during her first year had suffered from many feeding difficulties. She was very small for her age and microcephalic. The second child had a similar medical history. De Lange noted that the resemblance to each other was remarkable. She termed the condition "un type nouveau de dégénération (typus Amstelodamensis)." After she presented a further case to the Amsterdam Neurological Society, the disorder gained recognition by 1941 [3].

In a review in 1985, John Marius Opitz commented: "Brachmann's paper is a classic of Western Medical iconography, deserving to be commemorated in the eponym "Brachmann- de Lange syndrome." The conjoined description is now generally accepted, although the term "de Lange" or Cornelia de Lange's syndrome is also common [3].

To date there is no known cure although the syndrome can be managed by treating associated clinical symptoms. Sixty six percent of CdLS individuals die before the first year of life [4]. However, for those who survive infancy, life expectancy is relatively normal, reaching to the 6th decade. Nevertheless, certain features of this condition, particularly severe malformations of the heart or throat, decrease life expectancy dramatically. Mortality occurs primarily from aspiration in infancy and from infection and bowel obstruction in later years [4].

Overall, CdLS is probably under-diagnosed and frequently misdiagnosed and subsequently mismanaged.

CLINICAL FEATURES

As occurs in many other genetically flawed syndromes, strong resemblance is seen between people with CdLS. Distinctive facial features include thin confluent eyebrows (synophrys), long eyelashes, a short upturned nose, and thin downturned lips [5-7]. Prenatal and postnatal growth deficiency, psychomotor delay, and upper limb malformations are common. Birth weight is typically below 5lbs. Small stature and macrocephaly are also common. Although almost all organ systems can be affected, individuals with CdLS most notably display deficits in the development of neurosensory, craniofacial, musculoskeletal, cardiac, gastrointestinal and genitourinary systems. Medical concerns are also common and include gastro- esophageal reflux disease, heart defects, seizures, feeding difficulties, vision problems, and hearing loss. But CdLS is not a "one size fits all" condition. An individual may have many of the following traits, or only a select few. Geneticists and clinicians can establish the diagnosis after evaluating all the criteria. The Human Phenotype Ontology (HPO) provides a list of features that have been reported in people with CdeLS. Much of the information in the HPO comes from Orphanet, a European rare disease database. The list includes a rough estimate of the frequency of a feature. Frequencies are based on a specific study and may not be representative of all studies (Table 1).

Table 1. The approximate rate of occurrence of features found in CdeLS.
Adapted from (<https://rarediseases.info.nih.gov/diseases/10109/cornelia-de-lange-syndrome>) November 2017

Signs and Symptoms	Approximate number of patients (when available)
Abnormally low-pitched voice	Very frequent (present in 80%-99% of cases)
Anteverted nares	Very frequent (present in 80%-99% of cases)
Atresia of the external auditory canal	Very frequent (present in 80%-99% of cases)
Brachycephaly	Very frequent (present in 80%-99% of cases)
Curly eyelashes	Very frequent (present in 80%-99% of cases)
Poor dentition, delayed eruption	Very frequent (present in 80%-99% of cases)
Skeletal maturation slow	Very frequent (present in 80%-99% of cases)
Downturned corners of lips and mouth	Very frequent (present in 80%-99% of cases)
Gastroesophageal reflux	Very frequent (present in 80%-99% of cases)
Generalized hirsutism	Very frequent (present in 80%-99% of cases)

More organ specific diagnostic criteria are as follows.

Neuropsychiatric and Neurosensory

Hearing loss, including both sensorineural and conductive loss occur in up to 60% [6, 7]. Ear canals are narrowed or stenotic, making otitis media and sinusitis common complications [8, 9, 10]. Peripapillary pigmentation, high myopia, ptosis, microcornea, and blepharitis are also ophthalmologic problems [11]. Nasolacrimal duct obstruction, nystagmus, cataract and glaucoma are rarer findings.

Growth failure is apparent in over 95% beginning in utero and most obvious by six months of age with mean height and weight remain below the 5th percentile [6, 7]. Developmental delay, often severe, follows a similar path [12]. Overall IQ values range from below 30 to 102, with an average of 53 [13]. Patients with mild forms of CdLS have higher functioning with IQ that may be normal to borderline but are usually diagnosed with learning disabilities [12, 13, 14]. Disabilities in speech and language are common often leading to behavioral issues that may be secondary to frustration from an inability to communicate. Behavior is seen as consistent with depression and attention deficit hyperactivity disorder, and display obsessive-compulsive behavior, autistic behavior, including self- destructive tendencies, defiance, extreme shyness and avoidance of social interactions.

Craniofacial

As noted above, facial features are the most distinctive clinical feature. The characteristic facial phenotype is recognizable with the Facial Dysmorphology Novel Analysis (FDNA) technology [15]. The head is small, with a low hairline on the forehead and posterior neck. Eyebrows are well defined and confluent, and are highly arched in 98% of patients [5]. Eyelashes are long and thick with an exaggerated upward curve of the upper eyelashes and an exaggerated downward curve of the bottom eyelashes. Hypertelorism combined with an antimongoloid slant of the eyes is common. The midface is flattened and associated with a short nose and ante-verted nares. The nasal bridge is broad and/or depressed. The philtrum is long, smooth, and prominent. The lips are characteristically thin with downturned corners. Micrognathia and a high arched palate and cleft palate occur in 30% [5]. Dental anomalies are common and include widely spaced, small, absent or displaced teeth. Ears are low set, posteriorly rotated, and often hirsute.

Musculoskeletal

Specific extremity findings are a further aid to diagnosis. Although lower extremity findings are less common, over 80% of affected individuals have partial syndactyly of toes 2 and 3 [5]. Hands and feet are small in over 90%, and single palmar creases can be seen in 50% along with fifth finger clinodactyly in 75%, and brachydactyly [5]. The first metacarpal is often shortened with a proximally placed thumb [6]. Upper extremity malformations are seen in up to 30% of patients, and range from oligodactyly to ulnar deficiency to absent forearm. Misplaced diaphyses may develop distal to the elbow [6]. Radial head dislocation with abnormal elbow extension, clubbed feet and poikilothermia are also common. Pectus excavatum, scoliosis and hip dislocation or dysplasia have also been described. Missing arms, forearms, and/or fingers are found in 25% of patients with CdLS.

Cardiovascular and Pulmonary Findings

Congenital heart disease may be diagnosed in as many as 20 – 30%, compared to 0.8% for all births [5]. The most common abnormalities include (in descending order): ventricular septal defects, atrial septal defects, pulmonic stenosis, tetralogy of Fallot, hypoplastic left heart syndrome, and tricuspid aortic valve [16]. While some heart anomalies have obvious signs and symptoms at birth that prompt evaluation by a pediatric cardiologist other defects are more subtle and are not always recognized immediately, delaying detection. Children suspected of having CdLS should be screened by echocardiography.

Pulmonary hypoplasia and lobular anomalies predispose CdLS patients to respiratory infections. The most common causes of death in such patients are acute pneumonia and bronchitis. Pulmonary hypertension may result from repeated episodes of upper airway obstruction due to micrognathia and macroglossia exacerbating hypoxic and hypercapnic episodes

Gastrointestinal

The most common gastrointestinal complication is gastroesophageal reflux disease (GERD) occurring in over 90%⁶. Esophagitis, aspiration, chemical pneumonitis, and irritability are complications of GERD that can be avoided by diagnosis and treatment in the neonatal period. Pyloric stenosis with vomiting may contribute to malnutrition and poor weight gain during the neonatal period. Malrotation of the gut is less common but is still seen in at least 10% and may result in the life threatening situation of volvulus [6]. Congenital diaphragmatic hernia may also occur but the reported incidence may be underestimated as these infants often die in the perinatal period.

Genitourinary

Structural kidney and/or urinary tract anomalies, the most common being vesiculoureteral reflux, pelvic dilation and renal dysplasia associated with renal dysfunction, are found in up to 40% of individuals with CdLS [17]. Genitalia malformations include cryptorchidism occurring in up to 73% of males, with hypoplastic and micropenis in 57% and hypospadias [6]. Females may have small labia majora and abnormally formed uteri.

PATHOGENESIS AND CAUSES

Most cases of CdLS are due to spontaneous genetic mutations. Such mutations affecting the cohesin complex and multiple genes have been associated with CdLS. Researchers at the Children's Hospital of Philadelphia and the University of Newcastle upon Tyne identified a gene (NIPBL) on chromosome 5 that causes CdLS when it is mutated [18, 19]. In July 2012, a fourth "CdLS gene"—HDAC8—was announced. HDAC8 is an X-linked gene, meaning it is located on the X chromosome. Individuals with CdLS who have the gene change in HDAC8 make up only a small portion of all people with CdLS [20].

These genes, (NIPBL, SMC1A, SMC3), are all involved in sister chromatid cohesion. Cohesion proteins are required for chromosome segregation, regulation of gene expression, DNA repair and maintenance of genome stability. Mutations in NIPBL on chromosome 5 account for ~ 50% of CdLS cases, while mutations in SMC1A on the inactivated X chromosome, and SMC3 on chromosome 10 account for ~5% [21]. NIPBL and SMC3 mutations are both believed to have an autosomal dominant inheritance. SMC1A mutations may have an X-linked dominant pattern of inheritance, however males and females are affected similarly [22]. The genotype-phenotype correlation reveals that mutations in NIPBL result in more severe phenotypes than mutations in SMC1A and SMC3 genes that may often result in less severe expression [23]. Associated phenotype in NIPBL mutations increases in severity as the severity of the mutation increases. More severe mutations occur in NIPBL deletions or truncations, while milder forms of CdLS occur in patients with NIPBL missense mutations. (SMC1A and SMC3 gene mutations are predominantly missense and small in-frame deletions). The phenotype in patients with SMC1A and SMC3 mutations is milder, resulting mainly in mild to moderate mental retardation, with little growth retardation and limb or systemic

involvement [23]. However, a recent study indicated that CDL caused by a SMC 1A variant may be a responsible for neglected syndromic craniosynostosis [24]. Although mutations in these genes are implicated in 65% of patients, the pathogenesis of most cases of CdLS is sporadic and dominant [21].

Nevertheless this complex multisystem developmental disorder is caused by mutations in cohesin subunits and regulators, the precise molecular mechanisms are not well defined. However, identification points to a global deregulation of the transcriptional gene expression program. Cohesin is associated with the boundaries of chromosome domains and with enhancer and promoter regions connecting the three-dimensional genome organization with transcriptional regulation. A recent study that connected gene communities, and structures emerging from the interactions of non-coding regulatory elements and genes in the three-dimensional chromosomal space, provided a molecular explanation for the pathophysiology of CdLS associated with mutations in the cohesin-loading factor *NIPBL* and the cohesin subunit *SMC1A* *NIPBL* [25]. Genes deregulated in CdLS are positioned within reach of *NIPBL*- and cohesin-occupied regions through promoter-promoter interactions. The researchers offer a dynamic model where *NIPBL* loads cohesin to connect genes in communities, offering an explanation for the gene expression deregulation in the CdLS.

Other genes are probably also responsible when they mutate making it possible to understand why CdLS varies so widely from one individual to another and what can be done to improve the quality of life for people with the syndrome as they age [26].

Table 2. The latter two genes seem to correlate with a milder form of the syndrome (adapted from Wikipedia, accessed November 2017)

Name	OMIM	Gene	Appx. %	Notes
CDLS1	122470	NIPBL	50%	A gene responsible for CdLS on chromosome 5 was discovered in 2004 jointly by researchers at the Children’s Hospital of Philadelphia, and researchers at Newcastle University, UK.[7]
CDLS2	300590	SMC1A	5%	In 2006, a second gene, on the X chromosome, was found by Italian scientists.
CDLS3	610759	SMC3	1%	A third gene discovery was announced in 2007. The gene is on chromosome 10 and was also discovered by the research team in Philadelphia.

DIAGNOSIS

The diagnosis of CdLS is primarily a clinical one, based on medical signs that are evident from a medical history, physical examination, and laboratory tests. Since 2006, testing for *NIPBL* and *SMC1A* has been available through the University of Chicago [27]. Such testing is best accomplished through referral to a genetics specialist or clinic.

TREATMENT

There is no known cure. Because CdLS affects so many different systems of the body, medical management requires a team approach. Treatment varies based on the signs and symptoms presented. For example, poor growth after birth may require supplemental formulas and/or gastrostomy tube placement to meet nutritional needs and/or to decrease pulmonary complications from gastric aspiration. Ongoing physical, occupational, and speech therapies are recommended to improve developmental potential. Medications may be required to prevent or control seizures.

Surgery may be necessary to treat skeletal abnormalities, gastrointestinal problems, congenital heart defects and other health problems. General anesthesia is usually indicated because of poor cooperation and mental retardation especially in children and should be provided by an individual who is experienced in this condition as many problems associated with the procedure have been identified [28]. Antibiotic coverage and aspiration prophylaxis are essential. Structural renal defects are found in 40% and alter drug excretion. Securing the airway may be difficult and a smaller size tube indicated with the immediate availability of a difficult airway cart. Sedatives used as premedication may cause airway obstruction. Response to many drugs may be unpredictable secondary to endocrine disorders.

Support organization information should be given to the family whenever a diagnosis is made: the CdLS Foundation, 1-800-753-2357, www.CdLSusa.org. The CdLS foundation offers cards that are age specific of treatment options as follows [29, 30]:

1. *Infancy and at the time of diagnosis.* A karyotype should be obtained (blood chromosomes analysis sent and evaluated), although it will typically be normal. If a diagnosis is made, several studies and services are recommended including;
2. Echocardiogram, renal ultrasound, pediatric ophthalmologic evaluation with cycloplegic refraction, audiology evaluation (otoacoustic emissions, or brainstem auditory evoked response if audiology is abnormal), upper GI series to rule out malrotation and reflux, evaluation for GERD including pH probe and/or endoscopy, if positive and may require prokinetics or surgical correction with Nissen fundoplication or insertion of a gastrostomy tube, developmental assessment in infancy and continuing every one to three years, early intervention services initiated and continued as long as needed. Growth assessment should use appropriate CdLS growth charts. Treatment with high calorie formulas is often suggested, and may help with weight gain, but, individuals with CdLS appear to grow at their own pace with a high metabolic rate. Molecular testing should be available if parents are interested in further pregnancies and prenatal diagnosis options.
3. *Early Childhood (one to eight years old)* Regular evaluations and immunizations with the primary care provider are indicated. Cryptorchidism should be repaired by 18 months. Developmental services, with school placement and therapy issues should be individualized as most individuals will benefit from physical, occupational and speech therapy. The use of sign language facilitates oral communication. Growth should be monitored via CdLS-specific growth charts. Pediatric dentistry evaluation is

recommended q 6 months. Pediatric ophthalmology evaluation once or annually, should be done if indicated by findings on the first examination. Audiology testing is required every two to three years. Should there be clinical suspicion of worsening or initial signs of GERD, a repeat evaluation should be performed. Endoscopy has the greatest yield, but pH probe could be considered. Signs of potential volvulus such as bilious emesis or bilious withdrawal from the gastrostomy tube or sudden acute abdominal pain is an emergency and may require surgery. All subspecialties should become involved.

4. *Late Childhood (eight years – puberty)* Regular care through the primary care provider is indicated. Orthopedic involvement may be needed for joint contractures, hip complications, bunions, development of scoliosis, or orthotic use. Behavioral assessment includes assessment for ADHD and self-injurious behavior. Ongoing developmental services, with school placement and therapy issues as individualized are indicated. Again, most individuals benefit from physical, occupational and speech therapy. The use of sign language is encouraged to facilitate oral communication. Growth via CdLS-specific growth charts should be monitored as well as periodic dental audiologic and visual assessments. With any clinical suspicion of worsening or initial signs of GERD, a repeat evaluation should be performed. As before, endoscopy will often have the greatest yield, but pH probe could be considered.
5. *Adolescence (puberty – 20 years)* Regular care through the primary care provider is again emphasized with ongoing developmental services. School placement and therapy issues should be individualized. Plans should be initiated early for school or workplace placement after high school with job training and/or higher education. Pelvic examination with Pap smear regularly, or at least every three years, depending on sexual activity, from late adolescence throughout adulthood is indicated for females. Hormonal therapy with patient and family, both from the pregnancy prevention point of view, and management of menstruation (individualized to specific patient and family) should be discussed and recurrence risks identified if developmentally appropriate. Orthopedic involvement may be needed for joint contractures, hip complications, bunions, development of scoliosis, or orthotic use. Behavioral assessment includes ADHD and self-injurious behavior. Physical, occupational and speech therapy are still indicated. Growth via CdLS-specific growth charts should be monitored. Dental, eye and hearing evaluation should continue every 6months- 1 year as indicated. Worsening of GI symptoms must be immediately evaluated.
6. *Adulthood* Regular evaluations with primary care provider should continue, following blood pressure, baseline EKG, routine breast, or testicular and prostate examination as per usual medical guidelines. Job training or work issues, higher education should be discussed as well as behavioral or psychiatric assessment, including ADHD, obsessive-compulsive symptoms, self-injurious behavior, depression. A DEXA scan can rule out osteoporosis. Dental evaluation should be made every four to six months, depending on compliance. Regular pelvic examination with Pap smear at least every

three years, would depend on sexual activity, from late adolescence throughout adulthood. Hormonal therapy with patient and family should be available. Orthopedic involvement may be needed for joint contractures, hip complications, bunions, development of scoliosis, or orthotic use. Ongoing developmental services, with school placement and therapy issues should be individualized and individuals will benefit from physical, occupational and speech therapy. Growth monitoring should continue as well as dental, eye and auditory monitoring with appropriate subspecialist consultation as needed.

SUPPORT SERVICES

The Cornelia de Lange Syndrome (CdLS) Foundation is a nonprofit, family support organization based in Avon, Connecticut, that exists to ensure early and accurate diagnosis of CdLS, promote research into the causes and manifestations of the syndrome, and help people with a diagnosis of CdLS, and others with similar characteristics, to make informed decisions throughout their lives [29]. More information may be obtained from <https://ghr.nlm.nih.gov/condition/cornelia-de-lange-syndrome>.

CONCLUSION

Although specific gene mutations can be found in some patients, genetic testing is usually reserved to confirm an already highly suspected CdLS diagnosis. At present there is no cure for CdLS, which can have wide expression. Treatment is symptomatic and therapy based. Early intervention by means of medical and surgical care is necessary for feeding difficulties, congenital heart disease, urinary, auditory and visual abnormalities, as well as psychomotor delay. The CdLS foundation can provide invaluable support and management to patients and their families for management of this syndrome.

COGNITIVE-BEHAVIORAL PHENOTYPE IN KLINEFELTER SYNDROME (KS) AND OTHER SEX CHROMOSOMAL ANEUPLOIDIES (SCAs): CLINICAL VARIABILITY

**A. P. Verri*, C. D'Angelo, A. Cremante, F. Clerici,
A. Mauri and C. Castelletti**

IRCCS National Neurological Institute "C. Mondino" Foundation,
Laboratorio di Psicologia Cognitivo-Comportamentale,
Pavia, Italy

ABSTRACT

Background: SCAs are the most frequently occurring chromosomal abnormalities with an incidence of 1 in 400 births. As the number of X chromosomes increases, the phenotypic severity increases as well and it is estimated that cognitive abilities decrease by 10–15 IQ points for each additional X chromosome.

Aim of this paper is to illustrate clinical variability of cognitive-behavioral phenotype in the different SCAs.

Design and Methods: The sample was composed by 53 subjects (mean age = 21.16 yrs., range: 13-54) with karyotype 47, XXY (73%), 49, XXXXY (7%), 48, XXYY (9%), mosaicism 47, XXY/48, XXXY (2%), 47, XYY (5%), 48, XXXY (2%), 49, XXXYY (2%).

Only 5 subjects have been diagnosed prenatally (4 KS and 1 XXYY).

Primary caregivers completed a comprehensive questionnaire detailing birth, medical, developmental and psychological history. Cognitive and behavioral assessment was performed with clinical interviews using DSM 5 criteria and psychometric questionnaires (WISC-R, WAIS-R, CPM, Token Test, VABS, SCL90, SCQ).

Twenty-one sex and age matched subjects karyotypically normal were also evaluated from the behavioural point of view.

Results: Mean IQ in typical KS was 87.45 ± 2 ds (sd = 20.12) range 45-123, VIQ 91.74 (sd = 19.55) range 50-130 and PIQ 86.87 (sd = 20.87) range 50-126.

* Corresponding Author's Email: annapia.verri@mondino.it (Neuropsychiatrist and Neurologist).

Mean IQ in other SCAs was 68.71 (sd = 20.81) range 45-106, VIQ 69.36 (sd = 21.97) range 47-113 and PIQ 74.72 (sd = 21.70) range 45-112.

In CPM KS subjects scored 27.75 (range 13-36) and 31.50 in the Token Test (range 21-35) while in CPM the other SCAs subjects scored 22.27 (range 10-35) and 22.50 (range 9-31) in the Token Test ($p < .05$).

VABS scores documented more marked impairment on adaptive behavior in atypical SCAs subjects. SCL90 documented an elevation of paranoid scale in the 70% of KS subjects and 50% of other SCAs.

Autistic traits were present in 67% of the other SCAs subjects and in the 18% of KS at the SCQ.

Conclusion: A precise identification of the cognitive and behavioral phenotype in different SCAs may enhance the clinical treatment, anticipatory guidance, and care throughout the lifespan.

1. INTRODUCTION

Klinefelter's Syndrome (KS), described for the first time in 1942, is a genetic non-inherited pathology which is caused by an alteration of the number of sex chromosomes in male subjects. Patients affected by this syndrome have 47 chromosomes, due to the presence of one supernumerary X chromosome. This genetic anomaly influences sexual development and physical appearance, cognitive functions, motor and language development, and social skills. Cognitive abilities are typically in the average to low average range with weaknesses in verbal skills. Language difficulties are one of the most distinctive traits in cognitive functioning of people with KS. In fact, KS show an increased risk for developmental delays, speech-language disorders and learning disorders. Limitations in communication and behavioral aspects markedly affect social adaptation and the development of personality.

This prominent effects of the extra X chromosome on cognition, particularly in the language domain [1], has been documented also by fMRI studies. Measuring the patterns of brain activity during language processing in KS men, it was shown that language activity in the brain was less lateralized in the experimental group as compared to controls. It revealed an increased activity in the right hemisphere rather than reduced activity in the left hemisphere that causes a loss of asymmetric processing of language. The regions mostly involved was the Superior Temporal Gyrus (STG) and the supramarginal gyrus region, which is close to the posterior section of the STG and part of Wernicke's area. Reduced language laterality in the STG was highly correlated with the degree of disorganization of thought and language. Decreased functional asymmetry of language areas in the brain in XXY men may be secondary to abnormal X chromosomal inactivation [2].

Moreover, subjects with KS are predisposed to psychopathological risk. Behavior can include hyperactivity, attention problems, impulsivity, aggression, mood instability and autistic traits. In particular, Boks [3] observed the presence of a great variability of symptoms in a group of KS boys: learning disorders (65%), ADHD (63%), depressive disorders (24%), psychotic disorders (8%) and schizophrenia (2%). The risk of hospitalization for psychosis in adults KS is greater than in control subjects [4].

Some problems appear after the onset of puberty, when physical differences in KS become more evident and might result in body image disorders, sense of isolation and shame. Low self-esteem, anxiety, problems of socialization and mood disorders occur in boys with KS during

adolescence [5]. The presence of learning difficulties at school, mild cognitive impairment, problems in achieving good academic results often cause feelings of distrust even in childhood. The lack of integration within the peer group is the major source of anxiety and mood disorders. Many of the KS subjects seem to be more sensitive, anxious and insecure, and show a higher incidence of anxious-depressive disorders than the general population and an increased propensity to the use of drugs [5]. Some studies have emphasized that people with KS are friendly and open to interactions, do not usually have major problems with social interaction and adaptation, although they may be shy, sensitive and unassertive [6, 7]. Other studies have showed that males with KS have difficulties in the construction of satisfying social relationships, with antisocial behavior in adolescence and a more unstable occupational history, but a minority of them meet criteria for antisocial behavior disorder in adulthood [8].

KS is characterized by a constellation of physical symptoms: inadequate virilization, hypogonadism, azoospermia, infertility, gynecomastia, elevated average height (179.2 ± 6.2 cm) and increased plasma gonadotrophins [9], [10]. These problems are progressive and they begin to appear with more evidence during adolescence, in correspondence of sexual development.

Aneuploidy 47, XXY is the most common abnormality of sex chromosomes in humans, with an incidence equal to 1/450 male live births. About 80% of the KS patients show an XYY karyotype, but the 20% have other numeric sex chromosomes abnormalities (48, XXXY, 48, XXYY, 49, XXXXY, 46, XY/47, XXY mosaicism) or structurally abnormal sex chromosomes [11]. As the number of X chromosomes increases, the phenotypic severity increases as well and it is estimated that cognitive abilities decrease by 10–15 IQ points for each additional X chromosome [12].

The presence of one or more additional X chromosome(s) above the typical 46, XY in males leads to testicular dysgenesis and hypergonadotropic hypogonadism, and thus, 48, XXYY, 48, XXXY and 49, XXXXY are considered ‘variants’ of KS (47, XXY) because of these shared features. However, the increased risks for congenital malformations, additional medical problems and more complex psychological involvement in these other SCAs make distinction from 47, XXY important for these patients [12].

47, XXY (KS) is associated with tall stature, with studies reporting a mean adult height ranging from 179 to 188 cm. This characteristic is also of 48, XXXY and 48, XXYY males, in contrast, stature in males with 49, XXXXY syndrome is usually below average. A hypothesis is that the influence of extreme over dosage of sex chromosome genes in the pentasomic condition, affects multiple organ sites and growth pathways. Considering again the body habitus, other SCAs vary from being underweight to obese, and only approximately 30% have gynecomastia which is usually mild.

The degree of facial dysmorphism in all three syndromes is variable and often subtle, although dysmorphic features are typically more distinct in 49, XXXXY compared with 48, XXYY and 48, XXXY. Across all three conditions, common findings include hypertelorism, epicanthal folds, up-slanting palpebral fissures, hooded eyelids, significant dental problems. All of the findings above have also been described in 47, XXY, but they occur more frequently in other SCAs.

Developmental delays are common in infancy and early childhood, with speech delays, especially in expressive language, and motor delay associated with hypotonia, in almost all patients.

Visootsak et al., [7], using an adaptive functioning assessment (Vineland Adaptive Behavior Scales) in SCAs subjects, found that the mean standardized scores for adaptive functioning were in the disability range.

Other neurodevelopmental and psychological disorders are significant components of the phenotype of other SCAs and are typically more severe and/or complex when compared with typical KS. Developmental dyspraxia contributes to the early language and motor deficits. Attention Deficit Hyperactivity Disorder (ADHD) is present in over 70% of them, significantly higher than typical KS.

At the end, some emotional symptoms, as emotional immaturity, anxiety symptoms, obsessive-compulsive behaviours, impulsivity, behavioural dysregulation and tic disorders, are more commonly seen in these conditions compared with typical KS.

There is still little of knowledge about the cognitive behavioral phenotype of other SCAs. It's sure, anyway, that these patients are considered as a heterogeneous group with different and distinctive characteristics from typical KS. The focus of interest in the study of SCA was the genetics and the neurodevelopmental risk. Accumulating evidence that such genetic conditions not only impact physical development, but also psychological development, increased the awareness of the importance to study also psychological, emotional and behavioral problems [2]. The aim of this research is to compare a group of KS subjects and one with different SCAs, considering cognitive behavioral phenotype. In fact, some studies found that the number of supernumerary X negatively correlated with intellectual development and an increase of symptoms [13]. Moreover, we considered the history of epilepsy, autistic traits and psychosis as important variable of distinction between the two groups. We hypothesize that the other SCAs show more cognitive impairment and more developmental problems than typical KS.

2. PRESENT STUDY

The sample was composed by 53 adolescents and adults (mean age = 21.16 yrs, range: 13-54) with karyotype 47, XXY (73%), 49, XXXXY (7%), 48, XXYY (9%), mosaicism 47,XXY/48, XXXY(2%), 47,XXY (5%), 48, XXXY (2%), 49, XXXYY (2%) (Figure. 1; Table. 1).

These subjects were referred to the Laboratory of Cognitive Behavioral Psychology of the National Neurological Institute "C. Mondino" Foundation of Pavia, Italy. The inclusion criteria was first of all the genetic diagnosis of SCAs; moreover, the age: from all the Klinefelter subjects evaluated we chose patients from 13 years old. All the patients have been karyotyped using standard techniques, except two of them, who were diagnosed during a screening for intellectual disability, using the Array-Comparative Genomic Hybridation (CGH) molecular cytogenetic method.

Primary caregivers completed a comprehensive questionnaire detailing birth, medical, developmental and psychological history [14]. Cognitive and behavioral assessment was performed through a clinical interview made with the DSM-IV criteria and psychometric questionnaires. For the assessment of global cognitive functioning, Wechsler Scales (WISC-R - Wechsler Intelligence Scale for Children - Revised [15], WAIS-R – Wechsler Adult Intelligence Scale – Revised, [16] and Coloured Progressive Matrices (CPM) [17] were used.

The Token Test [18] was used to evaluate the ability of oral comprehension. The adaptive behaviour, the ability of personal and social self-sufficiency in real-life situations and the way in which cognitive abilities translate into management of self-autonomy in daily-life, were evaluated with The Vineland Adaptive Behaviour Scales (VABS) [19]. The Symptom Checklist (SCL-90-R) [20] is considered a valid instrument of general psychological distress in patients with experiencing a range of mental health and medical conditions. The Social Communication Questionnaire (SCQ) [21] offers a quick way to screen for Autism Spectrum Disorder. It was used to evaluate communicative, social and relational skills, and it was administered to parents. At last, (BSRI) [22] measured different aspects of psychological gender traits.

Figure 1. The graphic highlights other SCAs. Five subjects showed 48, XXYY karyotype, four 49, XXXXY, three 47, XYY and one 48, XXXY. One subject showed mosaicism (47, XXY/48, XXXY).

Table 1. Population

Karyotype	N	Mean age at first evaluation
47, XXY	39	24.43
Other SCAs	14	19.66
47, XYY	3	27
48, XXYY	5	20.8
48, XXXY	1	12
49, XXXXY	4	15.5
47, XXY/48, XXXY	1	23
Total	53	21.16

The table highlights mean age of the patients at first evaluation, grouped according to the karyotype.

Only 5 subjects have been diagnosed prenatally (4 KS and 1 XXYY) (Table 2 and 3).

Table 2. Age at diagnosis KS

Age at diagnosis	Percentage (n = 39)
Prenatal diagnosis	8,89% (4)
1-10 years	17,78% (8)
10- 18 years	35,56%(16)
18+ years	20%(9)

* 2 patients have not data.

Mean age of diagnosis across the entire group KS was 12, 89 years. The most frequent diagnosis was in the range of 10-18 years; prenatal diagnosis was the less frequent.

Table 3. Age at diagnosis other SCAs

Age at diagnosis	Percentage (n = 14)
Prenatal diagnosis	7,14% (1)
1-10 years	35,71% (6)
10- 18 years	42,86% (5)
18+ years	14,29% (2)

Mean age of diagnosis across the entire group other SCAs was 11,57 years. The most frequent diagnosis was in the range of 10-18 years; prenatal diagnosis was the less frequent.

A group of control, composed by twenty-one sex and age matched subjects, karyotypically normal, completed behavioral questionnaires (CPM, SCL90, BSRI). The statistical evaluation was carried out using the T-test and then we used the effect size Hedges' *g* to have a quantitative measure of the strength of the phenomenon, considering the different sizes of the groups.

3. RESULTS

3.1. Developmental and Clinical History

Anamnestic data (Table 4) confirmed the increased prevalence of psycho-motor delay in other SCAs as compared with typical KS.

The 70% of other SCAs show language delay, in contrast to only 30% of typical KS. Regarding as motor development, the 57% of other SCAs present a delay, compared with 15% of typical KS. Psychotic disorders emerged for the 40% of other SCAs, compared with 22,5% of typical KS. Epilepsy was diagnosed in the 25% of cases of other SCAs (66% of them were affected by generalized epilepsy, the others by focal) and in the 12,5% of typical KS (75% of them present generalized epilepsy, the others focal). Interestingly the 57% of subjects with epilepsy show also a psychotic disorder. On a statistic level, correlations with T-test confirmed a significant difference between the groups both for language delay ($t = .032$; $p < .05$) and for motor delay ($t = .013$; $p < .05$). The effect size for language delay was Hedges' *g* = 0.114765, while for motor delay was Hedges' *g* = 1.247012. Otherwise, for epilepsy and psychosis, between groups analysis didn't find out any significant difference (E: $t = .316$; P: $t = .158$), probably due to a large variability and heterogeneity into a too much small sample.

Table 4. Anamnestic data

* Neurodevelopmental and Previous Neuropsychiatric DIAGNOSES	KS (39)	“other SCAs” [14]
	%	%
Speech delay	33,33	64,28
Motor delay	17,95	50,01
Learning disability	35,90	57,14
Loneliness	41,02	64,28
epilepsy	12,50	25
ADHD	17,95	21,43
Impulse control disorder	30,77	35,71
Psychotic Disorder	22,50	40
Tic Disorder	10,26	14,28
Generalized anxiety disorder	35,90	35,71
Obsessive-compulsive disorder	15,38	42,86
Mood Disorders	35,90	21,43

*Anamnestic data.

The table highlights that other SCAs showed more frequent developmental problems compared to KS, except for generalized anxiety disorder and Mood Disorders, that were more frequent in KS.

3.2. DSM-IV Diagnosis

Considering the axis I disorders, 18% of typical KS and 21% of other SCAs present a diagnosis of ADHD, while the 36% of typical KS and the 58% of other SCAs show a diagnosis of Learning Disabilities. Psychotic Disorder emerged for the 40% of other SCAs, compared to 22,5% of typical KS. Finally, in the 50% of all patients, adaptive and behavioral problems and depressive or anxious traits were signaled.

On axis II, in the typical KS group, the 8% of patients are in the range of moderate-severe intellectual disability and the 17% of mild intellectual disability. Thirty-eight per cent of them showed an IQ level borderline, 24% were in the normal range and 13% present an IQ level higher than normal. In the other SCAs group, instead, the 31% of patients are in the range of moderate-severe intellectual disability and the 31% of mild intellectual disability. Twenty-three per cent of them showed an IQ level borderline, 15% were in the normal range and nobody presents an IQ level higher than normal.

3.3. IQ and Adaptive Behavior

Mean IQ in typical KS was $87,45 \pm 2$ sd (sd = 20,12) range 45-123, VIQ 91,74 (sd = 19,55) range 50-130 and PIQ 86,87 (sd = 20,87) range 50-126. Instead, mean IQ in other SCAs was 68, 71 (sd = 20,81) range 45-106, VIQ 69,36 (sd=21,97) range 47-113 and PIQ 74,72 (sd = 21,70) range 45-112 (Figures 2 and 3).

In CPM KS subjects obtained as mean score 27,75 (range 13-36, moda = 33) and 31,50 in the Token Test (range 21-35), while in CPM the SCAs subjects mean score was 22,27 (range 10-35, moda = 29) and 22,50 (range 9-31) in the Token Test.

Moreover, between groups analysis (t-test) identified significant differences between KS and other SCAs in mean IQ, lower in other SCAs ($p < .05$). The effect size for the mean IQ was Hedges' $g = 0.923239$, that means that the result went in the expected direction. In CPM, we found out a significant difference between KS/control group and other SCAs/control group ($p < .05$). In Token Test scores, a significant difference between groups was found ($p < .05$). The effect size was Hedges' $g = 6.121377$. Vineland scale scores documented more marked impairment in other SCAs subjects on adaptive behavior than in KS subjects ($p < .05$) (Figure 4).

In particular, for the other SCAs, communication, socialization and motor abilities resulted as weak points, compared to the average of normative population. Also for the typical KS, communication and motor abilities prove to be weak points, while socialization skills were worse than controls, but less compromised than in other SCAs. At the end, both for other SCAs and for typical KS, the daily-life abilities resulted as strong points.

Figure 2. Percentages of IQ levels for KS and for other SCAs. IQ is significantly higher in KS than in other SCAs.

Figure 3. The graphic shows results at the WAIS-R. KS obtained higher scores in all scales. The difference between groups was more evident in the verbal IQ.

Figure 4. The figure shows results of groups at the Token Test, VABS and CPM. In all tests other SCAs showed worse scores.

3.3.1. SCL-90

SCL90 documented an elevation of psychotic traits in KS/SCAs (about 50%) subjects in comparison with the control group (5%). There was also an elevation in somatization scale in KS subjects (58% KS, 16% other SCAs and 27% control groups), and in paranoid scale (70% for KS; 50% both for other SCAs and control group). However, there wasn't a statistical significant difference between the groups (Figure. 5).

Figure 5. This figure shows the results of the SCL-90. KS scores were higher in somatization, interpersonal sensitivity, anxiety, hostility, phobic anxiety and paranoid ideation scales, compared to other SCAs and controls. Other SCAs' scores were higher than the other groups in the obsessive-compulsive scale and in the psychoticism scales. Other SCAs showed a score approximately to the zero in the phobic anxiety. Controls' scores were higher in the depression scale and lower in the psychoticism scale, compared to other SCAs and KS.

3.3.2. SCQ

Considering the comorbidity between KS and ASD, reported by the literature [23], the SCQ was used to verify the presence of mild autistic traits. They were, in fact, present in 67% of the other SCAs subjects and in the 18% of KS. A statistical significant difference was found between the two groups. (Figure 6). The effect size was Hedges' $g = 1.002256$.

3.4. Bem Sex Role Inventory

In the feminine and masculine scales of BSRI profiles there was a significant difference between KS and other SCAs ($p<.05$). KS subjects show a low masculine scale in comparison with both SCAs and controls, while feminine scores are similar to controls. In other SCAs subjects the feminine scores were very low, while they showed a very high masculine scale. (Figure 7).

Figure 6. The graphic highlights that other SCAs showed more occurrence of autistic traits compared to KS.

Figure 7. Graphic highlights that other SCAs showed higher scores in the masculine scale, but in the feminine scale they obtained a score approximately to the zero. In the undifferentiated scale and in the androgynous scales, other SCAs scores were similar to controls. KS scores were quite homogeneous in each scale, except for the undifferentiated scale, where they got a higher score than controls and SCAs. In the androgynous scale, scores were very similar between the three groups.

4. DISCUSSION

The aneuploidy of the sex chromosomes is not usually associated with intellectual disability, but it is characterized by the presence of specific cognitive profiles. However, the cognitive level in KS proves to be in mean ten points lower than those of their brothers or peers [11]. The typical cognitive profile is mainly characterized by the presence of the discrepancy between scores on performance tasks and those achieved in the verbal subtests, in favor of the

former. Some studies have shown that verbal IQ scores are 10 points below the average compared with those of performance IQ [24]. This discrepancy may change during the life stages: differences in verbal conceptual and non verbal reasoning skills may diminish over time, with the former no longer being such an area of deficit. In our sample, mean IQ in typical KS was 87,45, in a range of normality/low average. Unlike what suggested in literature, mean of VIQ (91,74) was higher than mean of PIQ (86,87). This could be due to the use of alternative strategies for problem solving that require the use of verbal reasoning ability, learned through experience to compensate for their present difficulties, or may even be linked to the effects of hormonal therapies [24]. On the other hand, in our other SCAs subjects, mean IQ was 68,71, VIQ was 69,36 and PIQ was 74,72, in line with previous studies. Moreover this data confirm our hypothesis: the other SCAs show a lower IQ than typical KS. Other SCAs present an highlighted language, motor and social delay during the development, and a greater incidence of seizures and psychotic disorders. These data are consistent with literature. In fact, it was found that the number of supernumerary X negatively correlated with intellectual disability and an increase of symptoms [13]. Through parents' interviews, we found that a motor delay in the acquisition of first steps was more marked for other SCAs (about 19 months) than typical KS (about 14 months) (Table 4).

Adaptive functioning skills were found to be significantly lower than IQ in most cases, with a mean adaptive functioning in the disability range. These findings indicate that overall daily functioning is often more impaired than would be expected based on cognitive (IQ) scores. While the factors involved in the discrepancy between cognitive abilities and adaptive functioning deficits are not fully understood, these deficits contribute to the disability and prevent many individuals from achieving academic and occupational success [12].

A frequent problem reported by the patients were the seizures, documented by clinical history. Epilepsy was diagnosed in the 25% of cases of other SCAs and in the 12,5% of typical KS. The incidence is higher for other SCAs in comparison to typical KS. In fact, it is known that epilepsy is a common health problem among people with Intellectual Disability (ID). The estimated prevalence of epilepsy in people with ID ranges from 15-30%, while the prevalence of epilepsy in the general population is estimated at 0.6–1% [25].

Seizures in KS and in other SCAs are rare [26-28]. Probably we have found a higher incidence because our laboratory is located in an Institute for neurology. Cognitive functioning of KS subjects is characterized by the difficulty in expressive language. Language difficulties have been identified in 70-80% of children with KS at an early age [29]. Language difficulties include delay in onset of first words and in acquisition of the main stages of language development, in reading, expression, writing and reasoning abilities in arithmetic. Children with KS show difficulties in expression, inability to communicate their thoughts, ideas and emotions; otherwise the comprehension ability is in the standard. Often, during the developmental age, these problems are framed in learning disabilities as dyslexia and dysorthography [30]. Receptive language deficits have also been noted. Problems with phonemic discrimination, processing speed and comprehension of grammatical and morphological aspects of language have been reported [31-34]. Limitations in material processing speed and memory of auditory verbal material, which are associated with problems in decoding words, have been found in individuals with KS.

In our sample, these data were confirmed already by parents' reports. Both typical KS and other SCAs showed a delay in the acquisition of first words in comparison with typical children (typical KS: 16 months; other SCAs 17 months). Consequently the production of the first

sentences results difficult and slow, in fact, in our sample, children of both groups have reached this ability at about 31 months of age. It's obvious that there is a deficit in expressive language already in early development. As reported above in the data of verbal IQ, this delay persists during the life span.

Early language difficulties influence social adaptation and behavior disorder, together with personality development [35].

Moreover, adults with KS displayed relative difficulties in discriminating emotions in tone of voice, and, to a lesser extent, in verbal content [2]. This finding suggests that the XXY chromosomal pattern may not only be associated with difficulties in semantic aspects of language, but with prosodic aspects, as well. This finding may contribute to the development of more comprehensive models addressing the role of the X chromosome in normal and abnormal development of social communication. In fact, the limitation in communication markedly affects social adaptation and behavioral aspects, as well as the development of personality, even if the literature is not unanimous in describing social traits and personality in KS.

The sex chromosome aneuploidies are considered a risk factor for psychosis and psychopathology [36-38]. A higher incidence of psychiatric disorders, as anxiety, depression, behavioral disorder and schizophrenia, has been documented in people with KS compared with general population [5, 39]. A recent study reported that 8% of KS meet criteria for psychotic disorder, 45% have isolated psychotic symptoms and 24% meet criteria for depressive disorder [40]. In our study, psychosis problems emerged for the 40% of other SCAs, and for the 22,5% of typical KS. The SCL-90 documented psychotic traits in about 50% of KS/SCAs subjects in comparison with 5% of control group. There was also an elevation in somatization and in paranoid scales. A risk for hospitalization for KS adults is higher than the controls [4]. Subjects with both KS and schizophrenia show structural and functional anomalies in the Central Nervous System [4]. Sex chromosome aneuploidy is considered a risk factor for the development of psychiatric disorder.

Neuroimaging studies have documented anomalies in the brain structures of boys and adults with KS, which correlated with the presence of psychosocial problems [41]. These psychopathological aspects may be partly explained by a psycho-neurological phenotype that includes grey matter deficits in the superior temporal gyrus, the orbitofrontal cortex and the inferior frontal gyrus, white matter anomalies, impaired executive functions with severe deficits in the inhibitory component, abnormal structure of amygdala, caudate and putamen [37, 42]. These alterations may be caused by excessive expression of genes that lie in the pseudo-autosomal regions of the X-chromosome [41]. Moreover, total brain volume in typical KS is 7-8% smaller than healthy age-matched controls, whereas a reduction of 20% in males with other SCAs was found [43]. These reductions suggests that the X chromosome influences overall brain volume to a greater extent than the number of sex chromosomes in total [43].

Considering the different aspects of personality, many of the KS people seem to be more sensitive, anxious and insecure, and show a higher incidence of anxious-depressive disorders than the general population and an increased propensity to the use of drugs [5]. Other studies have emphasize that people with KS are friendly and open to interactions, do not usually have major problems with social interaction and adaptation, although they may be shy, sensitive and unassertive [6, 44]. KS subjects have difficulties in the construction of satisfying social relationships, with antisocial behavior in adolescence and a more unstable occupational history, but a minority of them meet criteria for antisocial behavior disorder in adulthood [8]. Although

children with KS are reported by clinicians to be hyperactive and to show difficulties in concentration, some studies have showed that children with KS have a docile temperament and lower activity levels compared with unaffected peers [10].

Gives a measurement of psychological androgyny, or high levels of both masculinity and femininity, considering that gender roles may be defined as “expectations about what is appropriate behavior for each sex” [44, 45]. The masculine scale has items as aggressive, ambitious, analytical, competitive, dominant, forceful, individualistic, while the feminine scale’s items are for example affectionate, cheerful, compassionate, gentle, tender, sympathetic. Men with KS exhibit marked variations in phenotype, which may range from males with severe signs of androgen deficiency to normally virilized males. In our sample we found out an interesting statistical significant difference in the scores of BSRI between typical KS and other SCAs. In other SCAs subjects, the feminine scores were very low, quite approximately to the zero, while the masculine scores are high. On the contrary, typical KS presented a feminine scores quite similar to those of the controls, but they showed a low masculine scale.

Another important aspect in the KS phenotype, considering a neuropsychological perspective, is the impact on the area of social information processing. Men with KS are reported to have inaccurate perception of social-emotional cues and difficulties in expressing their emotions [46]. A study have showed that 27% of the boys with KS met criteria for autism spectrum disorders [40]. In fact, children with KS show significant impairments in social cognition, in particular, they present deficit in ToM (Theory of Mind) when compared with the typically developing children, with performance not different from children with ASD, independent of level of intellectual functioning, receptive and expressive language. Impaired ToM may result in social difficulties. Moreover, both KS and ASD, also show difficulties in facial affect recognition, specifically in identifying angry facial expressions [47]. However, this mentalizing deficit may be related to a different set of cognitive dysfunctions: a recent neuroimaging study, showed frontal deficits in KS group in contrast to amygdala deficits in the ASD group [47]. In our sample, autistic traits were present in 67% of the other SCAs subjects and in the 18% of KS at the SCQ, with a statistical significant difference between groups.

Taking in account of the variability of cognitive behavioral phenotype and considering the DSM-IV diagnosis of each patient, the incidence of diagnosis of Intellectual Disability, of ADHD and of Learning Disabilities, is higher for other SCAs than for typical KS. In the same way, also at a diagnostic level, the frame of SCAs subjects appears generally more compromised.

Our hypothesis has been confirmed: other SCAs show more impairment and more developmental problems than typical KS, taking into consideration their cognitive behavioral phenotype. Anyway the cognitive profile in KS is characterized by marked variability and this could be influenced also by an early diagnosis, useful in order to plan different types of rehabilitation, when the developmental disorders is evident from a clinical point of view. A treatment, when begins in early life, could prevent some difficulties and developmental risk, considered with specific regard to the language and subsequently with possible emotional and behavioral problems. In fact, KS subjects, who had prenatal diagnosis, develop learning and language disabilities in a lower proportion than patients diagnosed by chance [48].

A limit of the present study is to have not considered the correlation between the age of diagnosis and the different disabilities of patients. In relation to these medical and psychological different impairments, we did not analyze the influence of the medical complications (cardiological, gastric, bone problems) in the SCA subjects and their consequent

cognitive and behavioral phenotype [49]. Moreover, our sample is small and in the future it could be interesting to study more subjects. It could be also intriguing to consider the role of the medical treatment of the patients, when it is applied. In fact, the diagnosis and therapy of andrological diseases interact with fertility and sexuality that are more sensitive to psychological, educational, cultural, religious and social factor than any other body function. In KS patients, androgen effects on appearance and social characteristics are modulated by the androgen receptor CAGn polymorphism [41]. The CAGn length has a marked influence on the social status in Ks patients. Men with shorter CAGn, and so higher androgenic activity, present more fertility problems than endocrine disorders. These men are more likely to live with a partner because they are sufficiently virilized, and so then they could present with the desire for paternity. This frame could influence positively in particular the social and behavioral aspects of men with KS. It could be interesting analyze if also at an andrological level exists a significant difference between typical SCAs and other KS, that could condition their phenotype. At the end, in relation to the assumption of therapy, a limit of the present study could be the lack of consideration of its possible influence in particular on the BSRI scores.

CONCLUSION

Klinefelter's Syndrome (KS), is a genetic non-inherited pathology which influences sexual development and physical appearance, cognitive functions, motor and language development, and social skills. A high variability of cognitive and behavior features is a characteristic of different SCAs disorders. The present study confirmed that other SCAs demonstrate more impairment and more developmental problems than typical KS. As the number of X chromosomes increases, the phenotypic severity increases as well. The other SCAs show a lower IQ than typical KS. The same picture emerged for the other ability and problems taken into consideration: other SCAs present an highlighted language, motor and social delay during the development, and a greater possibility to succumb to episodes of seizures and to psychotic disorders. These data are consistent with literature. Taking into consideration the variability of cognitive behavioral phenotype and considering the DSM-IV diagnosis of each patient, the incidence of diagnosis of intellectual disability, of ADHD and of learning disabilities, is higher for other SCAs, as well as for autistic traits.

It appears obvious that the variability in cognitive behavioral phenotypes in KS is wide and future studies could continue to investigate the various problems. In fact, it is important to note that an early identification of the cognitive and behavioral phenotypes in all patients with KS, typical and atypical, may enhance the clinical treatment, anticipatory guidance, and care throughout the lifespan.

ABSTRACT

Transcranial direct current stimulation (tDCS) is a non-invasive, painless brain stimulation treatment that uses direct electrical currents of low intensity to stimulate specific parts of the brain. tDCS could both facilitate (anodic stimulation) and inhibit (catodic stimulation) specific areas of the brain (Ardolino, Bossi, Barbieri, & Priori, 2005), as many neurological and psychiatric disorders are linked to a hypofunction or hyperfunction of specific areas of the nervous system. Such phenomenon is based on two processes: rearrangement of functional neural circuits, and their reconstruction (Kaas, & Garraghty, 1989; Kandel, Schwartz, & Jessell, 2000).

In light of the studies mentioned above, it is assumed that tDCS can represent a useful tool to facilitate the process of neuroplasticity in subjects affected by chronic neurological diseases and genetic etiopathogenesis, such as Rett Syndrome (RTT). The aim of the present study is to examine the neurophysiological and cognitive effects of cognitive empowerment combined with tDCS in young girls and women with RTT, with chronic language impairments. Despite results in cognitive rehabilitation showing a positive trend,

the efficacy of specific intervention on articulated speech is less consolidated. Lack of current research on successful outcomes in language production prompted the current study, which focuses more on intervention of articulated speech and cognitive functions.

In this chapter, we propose an integrated intervention: tDCS and cognitive empowerment applied to language in order to boost speech production (new functional sounds and new words). Given that maximal gains are usually achieved when tDCS is coupled with behavioural training, we applied tDCS stimulation on Broca's area together with linguistic training. Fourteen young girls and women with RTT were randomly allocated into two subgroups: AtDCS ($n = 7$) or placebo tDCS ($n = 7$). tDCS was applied over Broca's area for a 20-minute session for ten consecutive days. During tDCS stimulation, speech rehabilitation was divided into two sessions: production of vowels and word associations, and discrimination between corresponding words and images. Neurophysiological and cognitive parameters were measured at baseline, post-training and one month after intervention.

Results show a general enhancement in language, motor coordination and neurophysiological parameters in the AtDCS group compared to the placebo group. The present study provides evidence that tDCS combined with cognitive empowerment can improve language abilities and motor coordination and foster brain plasticity in young girls and women with RTT. Hence, this study supports the role of tDCS stimulation as a new methodology in the rehabilitation of diseases with chronic impairment and genetic etiopathogenesis.

Keywords: tDCS stimulation, cognitive empowerment, neuroplasticity, Rett Syndrome, rare genetic disorders

1. INTRODUCTION

The human genome contains an estimated total of 20,000-25,000 genes that serve as blueprints for building all of our proteins (International Human Genome Sequencing Consortium, 2004). In diseases caused by a single gene, a mutation in just one of these genes may be responsible for a disease. Single-gene diseases run in families and can be dominant or recessive, and autosomal or sex-linked (Chial, 2008).

Rett Syndrome (RTT) is a rare childhood developmental disorder, characterized by a primary disturbance in neuronal development. Females are primarily affected (1/10,000, Chahrour & Zoghbi, 2007), although a few cases of males have been reported in literature (Leonard et al., 2001; Cohen et al., 2002). Its aetiology involves the genetic mutation of gene MECP2 on the X-chromosome (Amir et al., 1999; Guy, Hendrich, Holmes, Martin, & Bird, 2011). Neurological abnormalities in RTT appear in several behavioural and cognitive impairments such as stereotypies, loss of speech and hand skills, gait apraxia, irregular breathing with hyperventilation while awake, and frequent seizures (Fabio, Billeci et al., 2016; Fabio, Cardile et al., 2017; Fabio, Castelli, Antonietti, & Marchetti, 2009; 2013).

However, the core of phenotype symptoms includes severe linguistic and motor impairments. With reference to the recovery of cognitive functions in RTT, recent investigations in which patients with RTT received intensive cognitive rehabilitation showed that they can go beyond the stage of pre-intentional level of development. Moreover, several studies using cognitive empowerment have provided evidence for positive neuroplasticity, as well as for transfer of benefits to untrained cognitive abilities (Anderson et al., 2013; Anguera,

White-Schwoch, Parbery-Clark, & Kraus 2013). In addition, results in cognitive rehabilitation generally showing a positive trend (Fabio, Capri, et al., 2017; Fabio, Colombo, et al., 2014; Fabio, Giannatiempo, Antonietti, Budden, 2009; Fabio, Giannatiempo, Oliva, Murdaca, 2011).

Within the landscape of studies on the recovery of the cerebral functions, after neurological lesions or disorders, neurostimulation techniques have recently been adopted. These techniques can influence specific parts of the brain by activation or inhibition, and their functionality. Transcranial direct current stimulation (tDCS) is a non-invasive, painless brain stimulation treatment that uses direct electrical currents of low intensity to stimulate specific parts of the brain. tDCS can both facilitate (anodic stimulation) and inhibit (cathodic stimulation) specific areas of the brain (Ardolino, Bossi, Barbieri, & Priori, 2005), as many neurological and psychiatric disorders are linked to a hypofunction or hyperfunction of specific areas of the nervous system. Such phenomenon is based on two processes: rearrangement of functional neural circuits, and their reconstruction (Kaas, & Garraghty, 1989; Kandel, Schwartz, & Jessell, 2000).

In a study aimed at exploring how tDCS influences language networks, Fertonani, Rosani, Cotelli, et al., (2010) found that anodal stimulation on the left dorsolateral prefrontal cortex improves naming performance and speeds up verbal reaction times, whereas cathodal stimulation had actually no effect. By administering an attentive task, they excluded non-specific effects due to a general increase in arousal. The authors concluded that left dorsolateral stimulation of the prefrontal cortex belonged to the cerebral network dedicated to lexical retrieval/selection processing in naming.

In a combined EEG–tDCS study (Wirth et al., 2017), the authors traced the effects of tDCS over the left dorsal prefrontal cortex, testing electrophysiological and behavioural variables during evident picture naming. The authors used the semantic blocking paradigm in which lexical-semantic competition increases when subjects have to name pictures of objects displayed in a semantically homogeneous context (i.e., cherries among grapes, pears and oranges) and decreases when the target object appears among semantically unrelated objects (heterogeneous blocks containing for example, cherries among flies, a cocktail and a bed). Anodal tDCS induced modulations of behavioural and electrophysiological data. The authors concluded that electrophysiological variables could help to understand how prefrontal anodal tDCS influences language production.

Based on these insights, we assume that tDCS can represent a useful tool to facilitate the process of neuroplasticity in subjects affected by chronic neurological diseases and genetic etiopathogenesis, such as RTT. In this chapter, we describe one of our studies in which we used an integrated intervention: tDCS and cognitive empowerment applied to language in order to boost speech production (new functional sounds and new words). Given that maximal gains are usually achieved when tDCS is coupled with behavioural training (Reis, Schambra, Cohen, Buch, Fritsch, Zarah, et al., 2009; Vannorsdall, Schretlen, Andrejczuk, Ledoux, Bosley, Weaver, et al., 2012), we applied tDCS stimulation on Broca's area together with cognitive training. We examined the cognitive and neurophysiological effects of tDCS comparing two groups: one in which the participants with RTT received anodal stimulation and another in which they received placebo stimulation. We hypothesized that tDCS combined with cognitive empowerment can induce neurophysiological and cognitive effects. We predicted that tDCS combined with cognitive training would positively influence language skills and the power beta and alpha band activity in the participants receiving anodal stimulation compared to the placebo group.

2. CURRENT STUDY

2.1. Methods

2.1.1. Participants

Fourteen young girls and women with RTT were identified through specific inclusion and exclusion criteria and were invited to participate in this study. The participants aged from 10 to 40 years old (mean = 18.34 years, SD = 5.36) and were in a chronic phase with stable language, but poor speech production and no changes after the third stage. Their families had been contacted by the Italian Rett Association and Italian Union Rett Onlus. Written informed consent was obtained from parents prior to the experiments. The experiment was approved by the ethics committee of the Department of Cognitive Science, University of Messina.

2.2. Procedure

The design of this study was ABAA: pre-test assessment, AtDCS or placebo tDCS and cognitive empowerment (speech rehabilitation), post-test assessment (ten days after the experiment) and follow-up assessment (one month after the experiment). In the pre-test phase, all participants underwent a neurological (EEG measure) and neuropsychological assessment to evaluate behavioural measures and linguistic pre-requisites prior to beginning the experiment. The scores obtained in the pre-test phase were compared with those observed in the post-treatment assessment phase and follow-up, to evaluate the effects of integrated intervention. In the neuropsychological assessment, the Vineland Adaptive Behavior Scales-Interview second edition (VABS) (Sparrow, Balla & Cicchetti, 1984), the Rett Assessment Rating Scales (RARS) (Fabio, Martinazzoli, & Antonietti, 2005), Fanzago's test (1983) and Raven's Progressive Matrices were used. VABS is a standardized semi-structured interview instrument that assesses day-to-day adaptive functioning and is administered to primary caregivers by fully trained research assistants in Vineland interview and scoring procedures. It consists of four domains: Communication (Receptive, Expressive, Written); Daily Living (Personal, Domestic, Community); Socialization (Interpersonal Relationships, Play and Leisure Time, Coping Skills); and Motor Skills (Gross, Fine). RARS is used to evaluate symptom severity in girls with Rett syndrome (Fabio, Martinazzoli, & Antonietti, 2005). The items in RARS were formed following the diagnostic criteria for RTT proposed by DSM-IV-TR (DSM-IV-TR; APA, 2000) and recent research. The Italian Fanzago phonetic articulation test (1983) evaluates the status of vocal sound articulation and objective production of articulated voice functional to communication. This instrument is based on spontaneous/repetition elicited from a denomination of 114 Figures grouped in 22 tables.

For cognitive measures, Modified Raven's Coloured Progressive Matrices were used (Antonietti et al., 2003). This test is made up of four series (A, B, C, D) of increasing complexity, with each series including 12 items (incomplete figures). The individual must complete an abstract figure choosing among six alternatives.

EEG data were acquired using a gold-standard digital EEG amplifier (Cardinal Medical System) of 21 electrodes placed on the scalp of the participant according to the expected parameters of the international measuring system 10/20. Quantitative analysis was performed

by tailor-made algorithms developed in Matlab code. The power spectral density (PSD) was evaluated by transforming the signal from the time domain to the frequency domain using the Welch method (Welch, 1967). A spectral analysis of EEG rhythms and the diffusion of the effect of the tDCS on all channels of registration were assessed. Neurophysiological and neuropsychological assessment was assessed at baseline (pre-test), ten days after the intervention and at one month after treatment.

2.3. tDCS Stimulation Protocol

Participants were randomly allocated into two subgroups: AtDCS ($n = 7$) or placebo tDCS ($n = 7$). In the AtDCS group, the participants received the integrated intervention anodal tDCS plus cognitive empowerment during the treatment phase. In the placebo tDCS group, participants received placebo stimulation plus cognitive empowerment. tDCS was administered at an intensity of two mA, using a stimulator connected to a pair of electrodes connected to a constant current stimulator (HDC type Company Stimulation Omicron T) isolated from the power supply as it has its own power supply (low voltage battery). The active electrode was placed on Broca's area, while the reference electrode was applied in the contralateral cephalic site. Speech rehabilitation was studied in two sessions: production of vowels and word associations, and discrimination between corresponding words and images.

2.4. Results

2.4.1. Comparative Analyses

The results indicate a steadily increasing trend in the production of new vowel/consonant sounds and words in the AtDCS group, as shown in Figures 1, 2, 3 and 4.

With reference to the motor coordination parameters, Figure 4 also shows a significant improvement of performance in the discrimination between corresponding words and images session. This suggests that tDCS combined with cognitive empowerment produces multiple effects: the plasticity of cortical structures has probably determined the cytoarchitecture reorganization of sub-cortical structures, such as the basal ganglia. It is well known that the basal ganglia form the extrapyramidal system which is involved in the control of complex motor actions, such as hand movement and phonetic production.

2.4.2. Statistical Analyses

Data were analysed using SPSS Version 14.0 for Windows. Descriptive statistics of the dependent variables were tabulated and examined. Alpha level was set to 0.05 for all statistical tests. In the case of significant effects, the effect size of the test was reported. ANOVA 2 (groups: atDCS vs placebo tDCS) $\times$ 4 (phases: pre-test, training, post-test and follow-up) was carried out.

With reference to groups, we found no significant effect, $F(3.25) = 4.84$; $p < .08$. There was significant groups $\times$ phases interaction, $F(3.27) = 19.21$; $p < .001$. This result indicates that the two groups show a different trend, as shown in Figure 1. In particular, the AtDCS group

shows a clear improvement in performance, whereas the placebo tDCS group presents a decrease in performance.

Figure 1. Number of vowels with elicited denomination for the two groups in the pre-test (A), training (B), post-test (A') and follow-up (A'') phases.

Figure 2. Number of consonants with elicited denomination for the two groups in the pre-test (A), training (B), post-test (A') and follow-up (A'') phases.

Figure 3. Number of vowels with elicited denomination for the two groups in the pre-test (A), training (B), post-test (A') and follow-up (A'') phases.

Figure 4. Trend of two groups related to the motor abilities in the pre-test (A), post-test (A') and follow-up (A'') phases.

2.4.3. Production of Vowels

Table 1 shows the means and standard deviations of the number of vowels with elicited denomination. The groups x phases interaction showed significant effects, $F(3,22) = 19.18$; $p < .001$. As shown in Figure 5, this result indicates that the AtDCS group shows a higher number of vowels than the placebo tDCS group. This trend remains stable in the post-test and follow-up phases.

Figure 5. Trend of two groups related to the production of vowels in the pre-test, post-test and follow-up phases.

Table 1. Means and standard deviation (SD) related to the production of vowels in the three phases

Groups	Pre-test	Post-test	Follow-up
AtDCS	1.25 (0,33)	3.19 (0,88)	3.1 (0,99)
Placebo tDCS	1.25 (0)	2.15 (0)	2.75 (0)

2.4.4. Production of Consonants

Table 2 shows the means and standard deviations of the number of consonants with elicited denomination. The groups x phases interaction shows significant effects, $F(3,27) = 19.21$; p

<.001. As shown in Figure 6, this result indicates that the AtDCS group shows a higher number of consonants compared to the placebo tDCS group. This trend remains stable in the post-test and follow-up phases.

Table 2. Means and standard deviation (SD) related to the production of consonants in the three phases

Groups	Pre-test	Post-test	Follow-up
AtDCS	1.5 (1,01)	3.15 (1,24)	3.4 (1.64)
Placebo tDCS	1.58 (0)	2.7 (0)	2.5 (0)

Figure 6. Trend of two groups related to the production of consonants in the pre-test, post-test and follow-up phases.

2.4.5. Production of Words

Table 3 shows the means and standard deviations of the number of words with elicited denomination. The groups x phases interaction shows significant effects, $F(3,27) = 2.95$; $p < .05$. As shown in Figure 7, this result indicates that the AtDCS group shows a higher number of words than the placebo tDCS group. This trend remains stable in post-test and follow-up phase.

Table 3. Means and standard deviation (SD) related to the production of words in the three phases

Groups	Pre-test	Post-test	Follow-up
AtDCS	1 (0.46)	3.16 (0.85)	3.29(1.16)
Placebo tDCS	1 (0)	2.6 (0)	3 (0)

Figures 7. Trend of two groups related to the production of words in the pre-test, post-test and follow-up phases.

2.4.6. Quantitative EEG Analysis

Quantitative analysis (QA) was performed by tailor made algorithms developed in Matlab code. The power spectral density (PSD) was evaluated by transforming the signal from the time domain to the frequency domain using the Welch method (Welch, 1967). PSDs were calculated for each epoch and were averaged. To begin with, the absolute total power of the signal and the absolute power of each band was calculated for each electrode. The considered bands were: theta (4 – 7 Hz), alpha (8 – 13 Hz) and beta (14 – 29 Hz).

As shown in Table 4, QA presents a significant rise in the frequency and power of alpha and beta bands and a decrease in pathological bands, such as theta.

Table 4. Quantitative analysis of rhythmic theta, beta and alpha related to pre-test, post-test and follow-up phases for the two groups

	Frequency bands	Pre-test (SD)	Post-test (SD)	Follow-up (SD)
AtDCS group	Theta (4 – 7 Hz)	6.1 (0.90)	7.9 (0.79)	7.2 (0.79)
	Beta (14 – 29 Hz)	14.2 (0.60)	21 (0.30)	19.8 (0.38)
	Alpha (8 – 13 Hz)	8.1 (0.75)	9 (0.73)	8.8 (0.73)
Placebo tDCS group	Theta (4 – 7 Hz)	6.3 (0.90)	6.5 (0.80) 14.1	6.2 (0.80)
	Beta (14 – 29 Hz)	13.9 (0.61)	(0.50)	15.3 (0.35)
	Alpha (8 – 13 Hz)	8.3 (0.75)	8 (0.73)	8 (0.73)

CONCLUSION

The aim of the present chapter was to examine the neurophysiological and cognitive effects of cognitive empowerment combined with tDCS in young girls and women with RTT with chronic language impairments. Here, we report our experimental study in which we adopted tDCS combined with cognitive empowerment in participants with RTT. The results of this study show a general enhancement in training abilities and neurophysiological parameters in the AtDCS group compared to the placebo group. Therefore, we can assume that cognitive empowerment combined with tDCS stimulation promotes neuroplasticity and facilitates the recovery of impaired functions in subjects with this rare genetic disease.

The ability of tDCS stimulation to induce changes in cortical function has been examined in a wide range of patients. Promising results have been reported with this approach in the treatment of neurological disorders, such as aphasia, Parkinson's, MCI, Alzheimer's disease, and subjects with focal brain injury, such as stroke (Martin et al., 2004; Falzone, Gangemi, & Fabio, 2015; Fabio, Gangemi, Caprì, Budden, & Falzone, in press; Fabio, Caprì, T., Lotan, Towey, & Martino, 2017). Hence, tDCS used alone or in combination with other approaches, like cognitive training, induces or modulates neuroplastic responses, demonstrates causal relations between brain and behaviour, translates into behavioural modification, and even leads to new therapeutic interventions (Bartrés-Faz & Vidal-Piñeiro, 2016). The results of the present study are in line with the research mentioned above. We propose that the efficacy of tDCS is due to the excitatory effect of the impulse on Broca's area which induces long-term enhancement (LPT) favouring the mechanisms of synaptic plasticity.

In conclusion, the results of the current study suggest that tDCS combined with cognitive training is a promising way to intervene and improve behaviours and brain activation in patients with RTT, and suggests the application of this kind of treatment in clinical practice.

CONTROL OF FORCE AND TIMING DURING UNIMANUAL AND BIMANUAL TAPPING MOVEMENTS OF ADOLESCENTS WITH DOWN SYNDROME

Nobuyuki Inui* and Junya Masumoto

Naruto University of Education, Japan

ABSTRACT

The present study examined the control of force and timing during finger tapping sequences of adolescents with Down syndrome. Data were obtained from two groups. An experimental group was composed of nine male adolescents with Down syndrome (15–17 years old). Two participants were moderate in intelligence level while other seven were severely intellectually disabled. A comparison group consisted of nine male high school students (16–17 years old). Participants performed both unimanual and bimanual tapping tasks with one self-paced test trial after three audible-synchronized practice trials with concurrent feedback of force output. All tasks consisted of a target force of 2N and a target intertap interval of 500 ms. Adolescents with Down syndrome exhibited a greater magnitude of positive constant error and variable error for peak force than typical adolescents. They also exhibited a greater magnitude of negative constant error and variable error for intertap interval than typical adolescents. Although normally developing comparison adolescents exhibited a linear relationship between peak force and press duration or time-to-peak force, the relationship was not familiar to adolescents with Down's syndrome. This may suggest differences in the manner of motor unit recruitment between the group with Down's syndrome and comparison adolescents. On the other hand, there was no difference between unimanual and bimanual tasks for variable error of intertap interval in adolescents with Down's syndrome. Because people with Down syndrome have exhibited a thinner corpus callosum than typical people, they may be unable to combine the output of two separate timing systems.

INTRODUCTION

A large body of research has found that people with Down syndrome move slower, less coordinated, and less accurately than the typical population (Anson and Mawston, 2000; Inui et al. 1995; Latash, 2000; Robertson et al. 2002). In particular, people with Down syndrome take longer reaction time to initiate a response to a stimulus (for review, Anson, 1992, Inui, 2007) and longer movement time to complete a motor task (for review, Latash, 1992).

The origin of perceptual-motor dysfunction in Down syndrome has been attributed to both structural and functional differences in the central nervous system. Structurally, individuals with Down syndrome have reduced volume in the cerebellum, hippocampus, and cerebral gray matter and white matter of the frontal cortex compared with age-matched non-Down syndrome peers (Teipel et al. 2004). Cerebellar atrophy has been suggested to be the most prominent structural difference underlying neuromotor impairment in Down syndrome (Latash, 2000).

In a simple reaction time setup (Anson and Mawston, 2000), whereas the electromyogram patterns for anterior deltoid and extensor indicis of the typical participants are “steplike,” those of participants with Down syndrome typically show a “ramplike” change in activation from baseline. In addition, whereas reaction times in typical participants are most often synchronized with the initial burst of muscle activity, those in individuals with Down syndrome often occurred after the initial burst of muscle activation. These findings have suggested differences between typical and Down’s syndrome persons for neuro-muscular system, being thought to be the reason that Down syndrome produces slower simple reaction times than in typical individuals.

Henderson et al. (1981) found that while children with Down syndrome had no difficulty with the spatial components of tracking and drawing tasks, they were impaired on the temporal aspects of tracking. Planinsek (1996) also observed that children with Down syndrome were slow in timing the grasp of the ball in simple catching tasks. Thus, individuals with Down syndrome may be unable to process and utilize predictable information and control timing of the onset and offset of muscular force. In particular, because individuals with Down syndrome are more dependent on response-produced feedback, they appear to be unable to acquire feedforward strategies with practice (Elliott, 1990; Elliott et al. 2010).

Charlton et al. (1996) and Vimercati et al. (2013) also reported that children or adults with Down syndrome relied on feedback control during a reaching or tapping task. Charlton et al. (1996) examined the kinematic characteristics of reaching to grasp in children with Down syndrome (mean age: 9 years) compared with both chronological age-matched and mental age-matched groups. Movement time, peak velocity of the wrist and number of movement units were analyzed. Number of movement units was derived from velocity profiles, and each movement unit consisted of a period of acceleration and deceleration. The results showed that children with Down syndrome moved slower and with reduced peak velocity, as found in previous studies (Latash, 2000). In addition, trajectories of children with Down syndrome exhibited greater irregularities and a greater number of movement units. The preprogramming part of the movement is spatially inaccurate for children with Down syndrome, causing the need for successive corrective movements and greater reliance on feedback. Charlton et al. (1996) thus pointed out that because feedback-based corrections take time, larger number of movement units was associated with longer durations of deceleration phase for children with Down syndrome. Vimercati et al. (2013) further examined movement strategies of adult participants

with Down syndrome and of age-matched controls during an arm tapping task. Participants with Down syndrome relied on feedback control.

On the other hand, many studies reported that persons with Down syndrome performed unimanual discrete movements (e.g., flip a switch) more accurately in visual instructions than in verbal instructions (Hartley, 1982; Elliot et al. 1987), proposing a model of atypical cerebral specialization (Elliot and Weeks, 1993). Using bimanual tapping movements, Elliott et al. (1986) reported that participants with Down syndrome were less lateralized for sequential processing although they performed more slowly than did comparison participants. However, some studies found that adults with Down syndrome performed bimanual continuous movements more accurately in auditory-motor, than verbal-motor (Robertson et al. 2002), or visual-motor (Ringenbach et al. 2002) situations. On a bimanual tapping task of a 3:2 polyrhythm, Inui and Asama (2003a, 2003b) found that because strong negative correlations between-hand taps were observed for adolescents with mental retardation, and their slow-hand movements were further subordinate to the movements of the fast hand, they adopted a hierarchical integrated organization. Although adolescents with autism or Down syndrome also participated in this or preliminary experiment, they were unable to meet the criteria in the test (recall) trials, and thus their data were not acquired.

There may be differences between unimanual and bimanual movements for movement organization in persons with Down syndrome. In addition, it can be anticipated that there are differences between typical and Down's syndrome persons for press duration and time-peak force in finger tapping sequences from the results of Anson and Mawston (2000). However, previous studies did not focus on the control of force and timing in tapping movements in the population with Down syndrome. Therefore, the present study examined the control of force and timing in both unimanual and bimanual tapping tasks to possibly reveal a different strategy for force control in adolescents with Down syndrome compared with typical adolescents (Masumoto et al. 2012).

METHOD

Participants

Data were obtained from two groups. An experimental group was composed of nine male adolescents with Down syndrome (15–17 years old) recruited from a high school for disabled children. Although their intelligence quotients could not be measured accurately, two participants were moderate in intelligence level while other seven were severe. A comparison group consisted of nine male high school students (16–17 years old). Handedness was tested using the Edinburgh Handedness Inventory (Oldfield, 1971). The laterality quotients of right-handed participants were +100 overall. Informed consent for participation in the experiment was obtained by parents of every participant. The procedures were approved by the ethics committee at Naruto University of Education, and the study was conducted according to the Declaration of Helsinki.

Apparatus and Measurements

Figure 1A showed that the outputs of the two load cells (Model LUB-5KB, Kyowa Electronic Instruments, Co., Tokyo, Japan; rated load 5 kg) used for finger tapping were amplified by a strain amplifier (Kyowa Model MCC-8A) and displayed on an oscilloscope (Model MD625BM-12, Leader Electronic Corp., Yokohama, Japan). The force output was also recorded by a personal computer (Apple PowerBook G4) and monitored on a screen (832 x 624 pixel resolution) after the amplified signal was converted from analogue to digital (PowerLab/8sp, AD Instruments, Dunedin, NZ). Data were sampled at a frequency of 1000 Hz by a 16 bit A/D converter with a low-pass filter of 100 Hz. In the task of finger tapping (Figure 1B), the peak force and intertap interval during each trial were measured using software for analysis of peak force, interval, press duration and time-to-peak force (Emile Soft Co., Ltd., Tokushima, Japan). The peak force of each tap was defined as the peak output voltage from the load cell. The intertap interval was defined as the onset-to-onset times of the tap. Press duration was defined as the time that a participant's finger was in contact with the load cell. Time-to-peak force was defined as the time to reach peak force. Press duration and time-to-peak force have been regarded as representative parameters of the time spent to accumulate force in a tapping movement (Piek et al. 1993).

Figure 1. Experimental setup in the task of bimanual tapping movement (A), and the definition and measurement of dependent variables (B).

Procedure

Participants were seated facing the two load cells, their palms resting on a support surface 6 cm in height from a table. In this posture, participants could make tapping movements by means of an extension-flexion pulse of the index finger at the metacarpophalangeal joint. All participants performed both unimanual and bimanual finger-tapping tasks, which consisted of producing a target force of 2N at a prescribed intertap interval of 500 ms. In a preliminary experiment of our previous studies (Inui and Asama, 2003a, 2003b), because a bimanual tapping task of a 3:2 polyrhythm was too difficult for adolescents with Down syndrome, they were unable to perform of the task. The present study thus adopted the task of bimanual finger-

tapping sequences. Half of the participants performed first the unimanual task whereas the other half performed first the bimanual task. Similarly, half of the participants performed first the unimanual task with the right hand whereas the remainder performed first the task with the left hand. In the unimanual tasks, they were instructed to match the target force at a prescribed intertap interval with either the right or the left hand, whereas in the bimanual task they had to match the target force and prescribed intertap interval with both hands simultaneously. Participants practiced each task separately, with the corresponding test trial immediately following three practice trials of 30 s each. During practice trials, the tapping rate was prescribed by means of an audible metronome (Model SQ100-88, Seiko Holdings Corp., Tokyo, Japan). The participants were instructed to synchronize finger taps on the one or two load cells with the metronome. The output of the load cell was displayed on an oscilloscope so that the participant could see the difference between the peak force produced and the target force, which was indicated on the oscilloscope by one or two horizontal lines. In the test trial immediately after the practice trials, participants tapped for 30 s only one time. They were instructed to produce the force and intertap interval acquired during practice by means of self-paced movement without feedback.

Statistical Analysis

In the analyses of the test trial, the dependent measures were constant error, variable error, press duration and time-to-peak force corresponding to the separate intertap interval and peak force produced. The constant error retained the sign of each error (the difference between the target and realized force or interval) when the average was calculated to produce an arithmetic mean error. The variable error was calculated as the standard deviation around the mean constant error for each participant. These values were calculated from 60 measures produced by each participant in each trial. In the analyses of the practice trials, on the other hand, data from the final trial were analyzed. A 2 (experimental vs. comparison group) $\times$ 2 (unimanual vs. bimanual task) $\times$ 2 (practice vs. test trial) $\times$ 2 (right vs. left hand) analysis of variance (ANOVA) was performed to examine the main effect of group, task, trial, and hand on the dependent measures. When significant overall condition effects were found for a dependent measure, post-hoc multiple comparisons were corrected using Tukey's honestly significant difference. Statistical significance was defined at the $p < 0.05$ level. To examine a linear relationship between peak force and press duration or time-to-peak force, correlations between peak force and press duration or time-to-peak force were calculated by means of all trials of both tasks performed by the typical or experimental group.

RESULTS

A main result of the present study is that adolescents with Down syndrome exhibited a greater magnitude of positive constant and variable errors for peak force than typical adolescents. Although there was no difference between groups for press duration, adolescents with Down syndrome exhibited a shorter time-to-peak force than typical adolescents. In

addition, there was no difference between unimanual and bimanual tasks for both constant and variable errors of peak force and intertap interval in adolescents with Down syndrome.

Figure 2. Constant errors (A and B), variable errors (C and D), and their standard deviations of peak force in both the unimanual and bimanual tasks (Masumoto et al., 2012). Abbreviations. CE: constant error, VE: variable error, Prac: practice trial, Test: test trial, Down: group with Down syndrome, Comparison: comparison group.

Figure 2 shows both constant error (A and B) and variable error (C and D) of peak force in both the unimanual and bimanual tasks. The constant error of peak force differed across group ($F(1, 128) = 9.72, p < 0.005$) but did not differ across task, trial, and hand. There was no interaction. Post hoc tests indicated that the experimental group exhibited a larger magnitude of positive constant error than the comparison group. The variable error of peak force differed across group ($F(1, 128) = 29.90, p < 0.0001$) and hand ($F(1, 128) = 4.96, p < 0.05$) but did not differ across task and trial. Post hoc tests indicated that the experimental group exhibited a larger magnitude of variable error than the comparison group and the left hand exhibited a larger magnitude of variable error than the right hand. The interaction of group and task was

further significant ($F(1, 128) = 4.28, p < 0.05$). Separate analyses on variable error showed that, although the experimental group exhibited a larger magnitude of variable error than the comparison group in the unimanual task, there was no difference between groups for variable error in the bimanual task.

Figure 3. Constant errors (A and B), variable errors (C and D), and their standard deviations of intertap interval in both the unimanual and bimanual tasks (Masumoto et al., 2012). Conventions are as shown in Figure 2.

To examine timing control for the target intertap interval, Figure 3 shows both constant error (A and B) and variable error (C and D) of intertap interval in both tasks. The constant error of intertap interval differed across group ($F(1, 128) = 12.36, p < 0.005$) and trial ($F(1, 128) = 5.27, p < 0.05$) but did not differ across task and hand. Post hoc tests indicated that the experimental group exhibited a larger magnitude of negative error than the comparison group and the test trial exhibited a larger magnitude of negative error than the practice trial. The interaction of group and trial was further significant ($F(1, 128) = 7.38, p < 0.01$). Separate analyses on constant error showed, although there was no difference between groups in the

practice trial, the experimental group exhibited negative errors in the test trial whereas the comparison group had positive errors. The variable error of intertap interval differed across group ($F(1, 128) = 31.23, p < 0.0001$) but did not differ task, trial, and hand. There was no interaction. Post hoc tests indicated that the experimental group exhibited a greater magnitude of variable error than the comparison group did.

To examine interactions of force and timing, Figures 4A and 4B show the mean and SD of press duration in both the tasks. The ANOVA on mean showed no significant main effects or interaction. Figures 4C and 4D show the mean and SD of time-to-peak force in both the tasks. The mean of time-to-peak force differed across group ($F(1, 128) = 60.13, p < 0.0001$) but did not differ task, trial, and hand. Post-hoc tests indicated that the comparison group exhibited a longer time than the experimental group. The interaction of group and hand was further significant ($F(1, 128) = 8.11, p < 0.005$). Separate analyses on mean showed that, although the left hand of the comparison group had a longer time than the right hand of the group, there was no left-right difference for the time of the experimental group.

Figure 4. Means and standard deviations of press duration (A and B) and time-to-peak force (C and D) in both the unimanual and bimanual tasks. Conventions are as shown in Figure 2.

To examine a linear relationship between peak force and press duration or time-to-peak force, correlations between peak force and press duration or time-to-peak force were calculated as follows: peak force vs press duration (comparison, $r(70) = 0.32$, $p < 0.01$, experimental, $r(70) = 0.19$, *ns*), peak force vs time-to-peak force (comparison, $r(70) = 0.29$, $p < 0.05$, experimental, $r(70) = 0.21$, *ns*). Although the comparison group exhibited a linear relationship between peak force and press duration or time-to-peak force, the relationship was not familiar to the experimental group.

To examine the lead-lag relationship between the left and right hands in the bimanual task, the mean and SD of the left-right difference for the tapping onset were measured. Although the left hand proceeded to the right hand for the comparison group in the mean of the test trial, the experimental group showed the opposite result for both trials. However the ANOVA on mean and SD showed no significant main effects or interactions.

DISCUSSION

A new finding of the present study is that adolescents with Down syndrome exhibited a greater magnitude of positive constant and variable errors for peak force than typical adolescents. Although there was no difference between groups for press duration, adolescents with Down syndrome exhibited a shorter time-to-peak force than typical adolescents. Whereas typical adolescents exhibited a linear relationship between peak force and press duration or time-to-peak force (also see Ivry, 1986), the relationship was not familiar to Down's syndrome adolescents. Piek et al. (1993) pointed out that because press duration was affected by the direction of the force change, the duration could be attributed to a mechanical aspect of the force change, namely recruitment of motor units or increased motor unit firing rates. Hence, the results of the present study may suggest differences in the manner of motor unit recruitment between typical and Down's syndrome adolescents.

For Down's syndrome persons compared to typical persons, whereas the present study found greater magnitude for peak force in the finger tapping movement, the lower maximal force production was reported by single finger tasks (Latash et al. 2002) and a handgrip task (Heffernan et al. 2009). The discrepancy between the present and previous studies may be influenced by the difference between force tasks. While the previous studies performed the maximal force production, the present study asked the participants to produce the target force with a prescribed interval. Participants did not need to control peak force and timing in the previous studies, but did those in the present study. Because the movement speed probably constrained Down's syndrome participants' performance for achieving the goal of the motor task in the current study, the participants appeared to overshoot the target force.

Heffernan et al. (2009) examined the structure of force variability for persons with Down syndrome in an isometric handgrip task at a constant force using a visual target. Although the experimental group exhibited lower mean force than the comparison group, the experimental group had more variable force than the comparison group. The experimental group further had a greater proportion of spectral power within the 0-4 Hz bandwidth than the comparison group. Using functional magnetic resonance imaging, Vaillancourt et al. (2006) found that increased force variability was associated with reduced cerebellar activity in an isometric force production task performed by typical adults. Because the low-frequency proportion of power

is related to sensorimotor feedback control (Vaillancourt and Newell, 2003), the increase in the low-frequency proportion reported by Heffernan et al. (2009) supports the hypothesis that deficits in cerebellar feed-forward processing are at least partially responsible for elevated force variability (Vaillancourt et al. 2006). In the present study, the adolescents with Down syndrome may have attenuated ability to anticipate the effects of a voluntary change in force. This attenuation may result in greater reliance on feedback processing as indicated by the elevated variable error and positive constant error of force.

On timing, the present study showed that adolescents with Down syndrome had greater magnitude of negative constant and variable errors of intertap interval than typical adolescents. The bimanual control of timing depends on interhemispheric or subcortical information processing. Bimanual coordination of continuous drawing of a circle depends on interhemispheric information processing across the corpus callosum (Spencer et al. 2003), whereas bimanual discrete tapping is controlled by the cerebellum (Kennerley et al. 2002), relating to intertap interval variability for adolescents with Down syndrome. On the other hand, Helmuth and Ivry (1996), asked participants to tap simultaneously with both hands and found less variability in timing with two hands, suggesting that the effect was due to combining the output of two separate timing systems. Masumoto and Inui (2012, 2013) show the same result as Helmuth and Ivry (1996) in bimanual isometric force production of normal male college students. In the present study, however, there was no difference between unimanual and bimanual tasks for variable error of intertap interval. The discrepancy between the previous and present studies may be influenced by the difference between typical and Down's syndrome individuals for the thickness of the corpus callosum. Because people with Down syndrome have exhibited a thinner corpus callosum than typical people (Wang et al. 1992), the problem appears to arise for Down's syndrome people in the transmission of information between cerebral hemispheres. Thus, Down's syndrome people may be unable to combine the output of two separate timing systems.

CONCLUSION

The purpose of this study is to examine the control of force and timing during unimanual and bimanual tapping movements. Adolescents with Down syndrome exhibited greater magnitude for peak force and a systematic delay on the onset of the movement. Although these results suggested differences in motor unit recruitment between Down's syndrome and typical adolescents, the physiological demonstration of this suggestion depends on the research hereafter. Contrary to our prediction, there was no difference for adolescents with Down's syndrome between unimanual and bimanual tasks for both constant and variable errors of peak force and intertap interval. Because people with Down syndrome have exhibited a thinner corpus callosum than typical people, they may be unable to combine the output of two separate timing systems.

ABSTRACT

We have shown promising results of Assisted Cycling Therapy (ACT) for improving executive functioning in adolescents with Down syndrome (DS). The current study examines the one month retention of executive function benefits gained by adolescents with DS. Fifteen participants were randomly assigned to voluntary cycling (VC; i.e., self-selected cadence) or Assisted Cycling Therapy (ACT; i.e., 65% faster than self-selected cadence accomplished by a motor). Both cycling groups rode a stationary bicycle, for 30 minutes, three times a week, for eight weeks. At the beginning (i.e., pre-test) and end (post-test) of the 8-week session, and at a one month retention (follow-up), three executive functions including set-switching, inhibition, and cognitive planning, were measured. The results showed improved cognitive planning and set-switching for the ACT group after 8 weeks of intervention and these improvements were maintained for one month after the intervention. However, no significant differences were found between the cycling groups for our measure of inhibition. Thus, our results suggest that, especially in regards to cognitive planning and set switching, ACT may lead to relatively permanent changes in the brain.

Keywords: Intellectual disability, treatment, cognitive planning, prefrontal cortex

INTRODUCTION

Down syndrome (DS), also known as Trisomy 21, is a chromosomal disorder in which a third copy of the 21st chromosome affects both structural and behavioral development of one in every 800 live births in the United States (Chapman & Hesketh, 2000). Intellectual disability is a hallmark in persons with DS. Executive function is a term used to describe a set of higher order cognitive processes beyond instinct or automatic responses that include inhibitory control, attentional control, and cognitive planning. These processes are crucial for selecting and monitoring behaviors to achieve goals of activities of daily living (e.g., brushing teeth, crossing the street, etc.). Research has shown that adolescents with DS display pervasive deficits in all domains of executive function (Lanfranchi, Jerman, Dal Pont, Alberty, & Vianello, 2010). Furthermore, these cognitive disabilities are a challenge and seem to limit their opportunities to physical activity participation (Cowley et al., 2010; Rhiitman et al., 2010).

Exercise may be an effective treatment for cognitive impairments because the positive influence of exercise on cognition has been demonstrated in other populations (e.g., elderly (Colcombe & Kramer, 2003; van Uffelen, Chin, Hopman-Rock, van Mechelen, 2008); typical children (Hillman, Erickson, & Kramer, 2003; Hillman, Snook, & Jerome, 2003)) and mice models (Ts65Dn) of DS (Llorens-Martin et al., 2010). There is an emerging body of literature in healthy older adults and individuals with Alzheimer's disease indicating that exercise results in structural and functional changes in the brain (Petzinger et al., 2006; Petzinger et al., 2007). These alterations in brain structure and function suggest that CNS function can be altered via voluntary exercise in individuals with relatively normal patterns of activation within the motor cortex. However, because persons with DS have limited motor output due to physiological and psychosocial factors, their ability to induce changes in CNS function may be compromised when engaging in voluntary exercise performed at their preferred (i.e., low) rates. For example, individuals with DS also display reduced exercise capacity which can hinder their ability to perform certain functional tasks or activities (Mendonca, Pereira, & Fernhall, 2010). Other physical characteristics can be particularly detrimental to the individual's participation in exercise and aerobic activities. For example, hypotonia and ligamentous laxity, cause shorter step length, increased knee flexion when walking, and decreased single-limb support (Lewis & Fragala-Pinkham, 2005). These physiological issues associated with DS make physical exertion more difficult. Whether caused by these physical limitations or their reduced cognitive function, individuals with DS are inherently prone to a more sedentary lifestyle (Jobling & Cuskelly, 2006) which creates an increased risk for obesity, diabetes, and cardiovascular disease (Lewis et al., 2005).

It is therefore necessary to employ assisted-exercise techniques and machinery in order to increase the rate of movement and subsequent potential cognitive benefits in this population. Though several studies have examined the effects of aerobic exercise on improving physical fitness, counteracting potential chronic disease risks, and improving executive function in typical populations (Smith et al., 2010; Warburton, Nicol, & Bredin, 2006), there is little-to-no research focused on the relationship between exercise and executive function in individuals with DS.

Animal studies have indicated that assisted-exercise, requiring an animal to exercise at a rate elevated from that at which it would exercise on its own, improves motor function and displays neuroprotective properties for Parkinson's disease (PD; Fisher, Petzinger, & Nixon,

2004). Similarly, researchers have found assisted aerobic exercise to improve cognitive function in human adults with Parkinson's disease (Ridgel, Kim, & Fickes, 2010). Recent research has demonstrated acute improvements in manual motor functioning and information processing in adolescents with DS after a single session of assisted cycling in comparison to voluntary cycling or no cycling (Ringenbach, Chen, Albert, Lichtsinn, & Alberts, 2013; Ringenbach, Albert, Chen, & Alberts, 2014). Benefits of long term assisted cycling on executive function in adolescents with DS have also been reported. Eight weeks of assisted cycling was associated with improvements in planning ability, inhibitory control, and reaction times (Holzapfel, Ringenbach, Mulvey, Sandoval-Menendez, Cook, Ganger, & Bennett, 2015; Ringenbach, Holzapfel, Mulvey, Jimenez, Benson, & Richter, 2016) in adolescents with DS. Voluntary cycling appeared to benefit set-switching and both assisted and voluntary cycling led to improvements in verbal fluency (Ringenbach et al., 2016). However, it has not been investigated whether these benefits are retained after the cessation of the cycling intervention.

Improvements in global motor function, that is, improvements in upper limb control after exercise in the lower limbs, and improvements in overall executive function following Assisted Cycling Therapy but not Voluntary Cycling suggest structural changes are occurring at the cortical level. In addition, the persistence of enhanced motor, cognitive, and clinical measures after the exercise intervention is stopped would indicate more permanent changes such as changes in the neural structure of the brain. Thus, we predict that, similar to patients with Parkinson's disease (Alberts, Linder, Penko, Lowe, & Phillips, 2011; Ridgel, Vitek, & Alberts, 2009), adolescents with DS will show improvements in executive function (i.e., cognitive planning, inhibition, and set-switching) following assisted, but not voluntary cycling after eight weeks, and that these changes will be maintained after one month of no cycling.

METHODS

Participants: Sixteen individuals with DS between the ages of 9 and 26, with a mean age of 18.6 years, completed this intervention (see Table 1). Though "adolescent" commonly refers to the teenage years, 13-19, it has been noted that physical, psychological, and cultural maturation can occur prior to or after this period (Coleman & Roker 1998). Due to the common delay of development within the DS population, this study refers to all participants between the ages of 9 and 26 as adolescents. Participants for this exercise intervention were recruited through fliers, email announcements, and by word of mouth from a variety of local organizations for persons with DS. For health and safety reasons all participants were screened for exercise preparedness prior to entering the intervention. Guardians were asked to complete a seven-question "Physical Activity Readiness Questionnaire" on behalf of the participant. Participants were considered cleared for exercise if all seven questions were answered as "no," or if specifically cleared for this study by their healthcare practitioner. The mental age of participants was assessed with the Peabody Picture Vocabulary Test 4 (PPVT-4; Dunn & Dunn, 2007). All protocols were approved by the Human Subjects Institutional Review Board of Arizona State University.

Table 1. Participant Characteristics

	ACT (n = 8)		VC (n = 7)	
	M	/F	M	/F
Gender	5	/3	3	/4
	Mean	± SD	Mean	± SD
Chronological age (years)	19.71	± 4.14	18.75	± 3.76
Mental age (years)	5.33	± 2.95	5.27	± 2.68

ACT = Assisted Cycling Therapy, BMI = Body mass index, VC = voluntary cycling.

Intervention: This study included two distinct and randomly assigned interventions: Assisted Cycling Therapy (ACT) and an active control intervention termed voluntary cycling (VC). The ACT group consisted of eight participants and the VC group consisted of seven participants. Both exercise groups completed three 30-minute cycling sessions per week for eight weeks. Participants were kept as close to this schedule as possible with an average span of participation of 9.34 weeks.

In the VC intervention, the mechanical motor of the stationary bicycle was not engaged. Participants pedaled at their own self-selected and self-regulated rate for 30 minutes. The ACT intervention utilized the mechanical motor of the bicycle to increase the cycling cadence. First, participants in the ACT group were asked to cycle at a self-selected rate for 5 minutes in order to warm up. This initial rate was then used to determine an accelerated rate at which the bicycle motor would be set; which was, on average, a 65% increase compared to the VC cadence (see Table 1). During the first ACT session, the motor was programmed to a cadence which was 35% faster than the voluntary warm-up cadence. This rate was generally increased in increments of 2-5 rpm as the 8-week intervention progressed to achieve a maximal cadence that the participants were comfortable maintaining.

Because this study focused on the benefits of aerobic exercise at varying rates of movement, it was important to ensure that the exercise intensity remained in the light to moderate aerobic intensity range. Heart rate was continuously monitored during the cycling sessions and the participants were instructed to slow down or the motor-assisted cadence was reduced if the heart rate exceeded 80% of the age-predicted maximal heart rate based on this formula: Age-predicted maximal heart rate = $210 - 0.56 \times \text{age} - 31$ (Fernhall et al., 2001).

Cognitive Testing: Participants completed three cognitive tests before (pre) and after (post) the 8-week session, as well as after their one month retention period (follow-up). These tests were designed to evaluate their cognitive planning, inhibition, and set-switching capabilities.

I. Cognitive Planning as measured by the “Tower of London” test: This test utilized a wooden platform with three pegs of graduating height and three wooden balls (blue, red, and yellow). The three pegs could accommodate a maximum of one, two, or three ball, respectively. The goal of each trial was to move the balls from their starting position to the final position, as depicted by a printed image, in the given number of moves and within the 45-second time limit. Participants were told to move only one ball at a time and that each move must end with the ball on one of the three pegs which still had available space. After one practice trial, participants moved through 17 different trials of increasing complexity and difficulty. Each trial was

considered a success if the participant achieved the goal arrangement in under 45 seconds and with the provided number of moves. The test was ended if the participant failed to complete four trials in a row, either due to time limitations, failure to follow the rules, or completing the trial in too many moves. The number of trials that were solved correctly within 45 seconds was used as the outcome measure.

II. Inhibition as measured by the “Knock-Tap” test: In the first trial, participants were shown how to knock (i.e., using their knuckles) and tap (i.e., using the palm of their hand) on the table at which they were seated across from the researcher. They were instructed to tap on the table each time the researcher knocked, and knock on the table each time the researcher tapped. A trial of 4 actions, two knocks and two taps, were performed with researcher prompting before the 15-action trial was performed. One point was awarded for each correct action for a maximum of 15 points. The second trial involved the actions of responding with a knock, fist, or no response; as was demonstrated by the researcher for the participant to mimic. Participants were asked to knock when the researcher made a fist, to make a fist when the researcher knocked, and to remain still (i.e., no active response) when the researcher tapped. There was a 6-action practice prior to the 15-action trial. A total of 30 points was possible after the combination of the two trials. The total number of correct responses/actions was used as the outcome measure.

III. Set-Switching as measured by the “Card Sorting” test: For the following two trials, the cards were always presented in a pre-determined order and the instructions were read from a pre-written script in order to minimize variation between researchers. Participants were reminded of the rules and shown an example of proper sorting for one card at the beginning of each trial. Each participant was presented with two trays; one held a card with a blue rabbit on the left-hand side and the other had a red boat on the right-hand side of the participant. For the first trial the participants were asked to sort six cards, depicting either a red rabbit or a blue boat, one-by-one, into the appropriate tray based on color (i.e., the red rabbit would go into the right-hand tray showing the red boat). Each card was placed face down in the tray to avoid patterned sorting. One point was awarded for each card placed in the proper tray, allowing for a maximum of six points. For the second trial, the participants were asked to sort the same six cards by shape rather than color (i.e., the red rabbit would go into the left-hand tray which showed a blue rabbit). This meant that participants had to cope with the rule switch of sorting by color to sorting by shape. Again, the cards were placed face down before the next card was shown, and a maximum of six points was awarded for correct placement. The number of correctly sorted cards during the second trial (sorting by shape) was used as the outcome measure of set-switching ability.

Statistical Procedures: All data were analyzed using a within-between subjects general linear model analysis. Time (pre, post, and follow-up) was the within-subjects factor and group (ACT and VC) was the between subjects factor. Next, the VC and ACT groups were analyzed independently using a one-way ANOVA with time as a fixed factor to examine differences between time points within each group. Tukey HSD post-hoc test were used for multiple comparisons between time points. Data was analyzed with the Statistical Package for the Social Sciences v. 23 (SPSS; IBM Corporation, Armonk, NY) and the null hypothesis was rejected at $p \leq 0.005$.

RESULTS

Cognitive Planning (Figure 1): The main effect of time for the number of correct trials approached conventional levels of significance ($F(2,26) = 2.90$, $p = 0.073$). There was a significant interaction between time and group ($F(2,26) = 5.01$, $p = 0.014$). The main effect of time was significant for the ACT group ($F(2,21) = 6.86$, $p = 0.005$) and post-hoc comparisons indicated a pre- to post-test improvement ($\bar{x}_{\text{post}} - \bar{x}_{\text{pre}} = 2.75$, $SE = 0.94$, $p = 0.022$), a pre- to follow-up improvement ($\bar{x}_{\text{follow-up}} - \bar{x}_{\text{pre}} = 3.25$, $SE = 0.94$, $p = 0.007$), and no change from post-testing to follow-up ($\bar{x}_{\text{follow-up}} - \bar{x}_{\text{post}} = 0.50$, $SE = 0.94$, $p = 0.858$) for the number of correct trials in the ACT group. The main effect of time was not significant for the VC group ($F(2,21) = 0.71$, $p = 0.504$) and post-hoc comparisons indicated no pre- to post-test change ($\bar{x}_{\text{post}} - \bar{x}_{\text{pre}} = -1.29$, $SE = 1.24$, $p = 0.566$), no pre- to follow-up change ($\bar{x}_{\text{follow-up}} - \bar{x}_{\text{pre}} = 0.00$, $SE = 1.24$, $p = 0.007$), and no change from post-testing to follow-up ($\bar{x}_{\text{follow-up}} - \bar{x}_{\text{post}} = 1.29$, $SE = 1.24$, $p = 0.858$) for the number of correct trials in the VC group.

Figure 1. Means and standard errors of successful “Tower of London” (e.g., cognitive planning) trials as a function of group and time. Brackets indicate significant differences based on post-hoc tests between the means they connect. ACT = Assisted Cycling Therapy, VC = voluntary cycling.

Inhibition (Figure 2): The main effect of time for the number of correct responses was significant ($F(2,26) = 3.82$, $p = 0.035$). There was no interaction between time and group ($F(2,26) = 0.17$, $p = 0.849$). The main effect of time was not significant for the ACT group ($F(2,21) = 0.18$, $p = 0.839$) and post-hoc comparisons indicated no pre- to post-test change ($\bar{x}_{\text{post}} - \bar{x}_{\text{pre}} = 2.50$, $SE = 5.11$, $p = 0.877$), no pre- to follow-up change ($\bar{x}_{\text{follow-up}} - \bar{x}_{\text{pre}} = 2.75$, $SE = 5.11$, $p = 0.853$), and no change from post-testing to follow-up ($\bar{x}_{\text{follow-up}} - \bar{x}_{\text{post}} = 0.25$, $SE = 5.11$, $p = 0.999$) for the number of correct responses in the ACT group. The main effect of time was not significant for the VC group ($F(2,21) = 0.20$, $p = 0.824$) and post-hoc comparisons indicated no change from pre- to post-test ($\bar{x}_{\text{post}} - \bar{x}_{\text{pre}} = 1.86$, $SE = 5.48$, $p = 0.939$), no change from pre-test to follow-up ($\bar{x}_{\text{follow-up}} - \bar{x}_{\text{pre}} = 3.43$, $SE = 5.48$, $p = 0.808$), and no change from post-testing to follow-up ($\bar{x}_{\text{follow-up}} - \bar{x}_{\text{post}} = 1.57$, $SE = 5.48$, $p = 0.956$) for the number of correct responses in the VC group. Although there was a main effect of time, the mean improvements in either group were not significant due to substantial error variance.

Figure 2. Means and standard errors of correct “Knock-Tap” (e.g., inhibitory control) responses as a function of group and time. ACT = Assisted Cycling Therapy, VC = voluntary cycling.

Figure 3. Means and standard errors of correctly sorted cards during the second trial (i.e., sort by shape) of the “Card Sorting Test” (i.e., set-switching) as a function of group and time. Brackets indicate significant differences based on post-hoc tests between the means they connect. ACT = Assisted Cycling Therapy, VC = voluntary cycling.

Set-Switching (Figure 3): The main effect of time for the number of correctly sorted cards was significant ($F(2,26) = 16.18, p < 0.001$). There was no interaction between time and group ($F(2,26) = 0.00, p = 1.000$). The main effect of time was significant for the ACT group ($F(2,21) = 12.11, p < 0.001$) and post-hoc comparisons indicated a pre- to post-test improvement ($\bar{x}_{\text{post}} - \bar{x}_{\text{pre}} = 1.00, SE = 0.23, p < 0.001$), a pre- to follow-up improvement ($\bar{x}_{\text{follow-up}} - \bar{x}_{\text{pre}} = 1.00, SE = 0.23, p < 0.001$), and no change from post-testing to follow-up ($\bar{x}_{\text{follow-up}} - \bar{x}_{\text{post}} = 0.00, SE = 0.23, p = 1.000$) for the number of correctly sorted cards in the ACT group. The main effect of time was not significant for the VC group ($F(2,21) = 2.33, p = 0.126$) and post-hoc comparisons indicated no change from pre- to post-test ($\bar{x}_{\text{post}} - \bar{x}_{\text{pre}} = 1.00, SE = 0.53, p = 0.176$), no change from pre-test to follow-up ($\bar{x}_{\text{follow-up}} - \bar{x}_{\text{pre}} = 1.00, SE = 0.53, p = 0.176$), and no change from post-testing to follow-up ($\bar{x}_{\text{follow-up}} - \bar{x}_{\text{post}} = 0.00, SE = 0.53, p = 1.000$) for the number of correctly sorted cards in the VC group. The mean improvement was the same for both groups, but the improvements in the ACT group reached statistical significance due to lower error variance.

DISCUSSION

This is the first study, to our knowledge, that has utilized a chronic (i.e., 8 week) between group intervention using Assisted Cycling Therapy (ACT) in adolescents with DS and measured changes in executive functioning. We believe it is also the first study reporting on the retention of improvements in executive function following an aerobic exercise intervention. Enhancing executive functioning is critical to improving activities of daily living (e.g., dressing, preparing food, self-care, etc.), fostering independence, and improving quality of life for persons with DS (Alptekin et al., 2005; Borella et al., 2010; Diamond, 2013; Evans & Gray, 2000; Holzapfel et al., 2015; Jefferson et al., 2006; Myers & Pueschel, 1991; Shaw et al., 2006; Wegener et al., 2005; Whitmer & Banich 2007).

Given that the brain of an individual with DS contains a reduced number of neurons and abnormal neuron morphology, especially in the cerebral cortex, it is not surprising that many persons with DS suffer some reduced executive functions (Reeves & Irving, 1995). This study aimed to improve executive function in three specific areas: planning, inhibition, and set-switching, and to observe the retention of improvements over a one month period. Though improvements were only observed in cognitive planning ability and set-switching ability, retention of post-intervention levels was observed in all three measures. The improvements were most evident following ACT which has been suggested to promote cognitive improvements in adolescents with DS (Holzapfel et al., 2015; Ringenbach et al., 2016). The data from this study are consistent with this finding that improvements may be more permanent (e.g., last at least 4 weeks), which may indicate changes at the neuronal level.

Our results show that cognitive planning and set-switching ability improved only in the ACT group (see Figures 1 and 3). The improvements from pre- to post-test were significant and the improvements were retained for 4 weeks following the post-test. No changes in cognitive planning or set-switching were observed in the VC group. There was a trend for improvements in inhibitory control across both groups (see Figure 2). The main effect of time was significant but there was no interaction between time and group. Within group improvements in inhibition did not reach significance.

Thus, improvements in executive function were greatest after ACT and improvements were generally maintained. The relative preservation of executive function improvements indicates neuroplastic changes in the prefrontal cortex (Alberts et al., 2011; Holzapfel et al., 2015; Ringenbach et al., 2016). Our results are consistent with many studies reporting the maintenance of executive function following cognitive intervention programs (Valenzuela & Sachdev, 2009; Wexler, 2007). However, exercise interventions do not always result in the retention of gains in executive function (Quaney et al., 2009) unless the exercise regimen is continued (Emery, Shermer, Hauck, Hsiao, & MacIntyre, 2003).

Aerobic exercise has been shown to increase cortical excitability and cerebral blood flow which are associated with the upregulation of dopamine, brain-derived neurotrophic factor, glial-derived neurotrophic factor, insulin-like growth factor, and vascular-endothelial derived growth factor (Alberts et al., 2011; Christensen et al., 2000; Cotman et al., 2007; Cotman & Engesser-Cesar, 2002; Nobrega et al., 1994; Piepmeier & Etnier, 2015; Tajiri et al., 2009; Tillerson, Caudle, Reveron, & Miller, 2003). These neurotrophic and growth factors regulate the growth and plasticity of neurons and growth and health of blood vessels which are the mechanisms that may explain the link between exercise and improvements in executive

function (Audiffren & André, 2015; Cotman et al., 2007; Piepmeier & Etnier, 2015). These relationships and mechanisms are illustrated in Figure 4 (Alberts et al., 2011).

The question that remains is why ACT seems to benefit executive function more than VC. The exercise intensities as measured by heart rate were similar between the ACT and VC group. The only difference was in the cadence and the nature of the movement production. The ACT cadence was on average 65% faster than the VC cadence (see Table 1) and the movement output was assisted during ACT. Greater frequencies of mechanical stimulation have been shown to elicit greater corticospinal excitability compared to lower frequencies (Christova et al., 2011). Similarly, the increased cycling cadence during ACT compared to VC may have enhanced the flexion and extension moments of force that are associated with cycling and thereby increased neural activity in the involved musculature (Ericson, 1985). The increased movement rate also resulted in more rapid muscle shortening and lengthening which is thought to stimulate velocity dependent muscle spindle fibers (Corbett et al., 2013). The increased proprioceptive input from these fibers may have enhanced corticospinal excitability (Alberts et al., 2011; Corbett et al., 2013) and thereby upregulated the activity of brain-derived neurotrophic factor, glial-derived neurotrophic factor, and vascular-endothelial derived neurotrophic factor (Alberts et al., 2011; Cotman et al., 2007; Piepmeier & Etnier, 2015; Tillerson, Caudle, Revereon, & Miller, 2003). Based on our results, these biochemical processes and resultant neuroplastic changes appear to be robust and temporally stable up to four weeks post-exercise in adolescents with DS.

Figure 4. Model of mechanisms involved in Assisted Cycling Therapy.

It may be that neuroplastic and perhaps vascular changes last longer in individuals with DS compared to other populations as we found retention of executive benefits whereas other studies did not, following an exercise intervention (Emery et al., 2003; Quaney et al., 2009). However, our follow-up period of four weeks is shorter compared to other studies and we do not know how much time after the exercise intervention would need to pass before executive functions return to baseline levels.

STRENGTHS AND LIMITATIONS

To the best of our knowledge, this is the first study which examined the effects of aerobic exercise on executive function and the retention of executive function benefits in persons with DS. Participants were randomized to two different types of cycling exercise, whereas VC served as an active rather than passive control group. However, a passive control group could have further informed the results by allowing for the quantification of a learning effect that may have taken place across the 12 weeks. The significant results, in spite of the limited sample size, indicate that the intervention effects were quite substantial. In fact, the improvements in measures of executive function ranged from 0.17 to 1.54 (Cohen's *d*) in the ACT group.

CONCLUSION

The present study examined an innovative exercise intervention that may be able to overcome low exercise capacities commonly seen in persons with DS by augmenting the movement rates during cycling exercise. The assisted nature of ACT may maximize neurological benefits of exercise, by compensating for the decreased motivation and slow movement rates in adolescents with DS. We found that ACT may improve cognitive function through potentially long-term changes to the brain's structure. The results of this study indicate that cognitive planning and set-switching may display long-term improvement after an 8-week ACT intervention. However, longer intervention periods may be needed to produce improvements in inhibitory control. It is unknown at this point whether the observed improvements would last longer than 4 weeks. This area of research could be further expanded to test dose-response relationships between cadence and executive functions and to develop an assisted exercise plan modeled directly towards managing executive function deficits in people with DS.

EDUCATION

1998, Ph.D., Purdue University, Department of Health, Kinesiology and Leisure Studies

1993, M.Sc., McMaster University, Department of Human Biodynamics

1991, B.Pe., McMaster University, Department of Physical Education

Professional Experience:

- 2013 – present Associate Dean, Barrett, The Honors College for the Downtown Phoenix Campus
- 2013 – present Affiliated Faculty, Cognitive Science, Department of Psychology, ASU
- 2005 – present Associate Professor, Program of Kinesiology, ASU
- 2001 - present Affiliated Faculty, Department of Psychology, ASU
- 2003 - 2005 Researcher, *The localization of Parkinsonian micrographia*, (Stelmach, G. E. S. (PI)), National Institute for Neurological Disorders and Stroke, ASU
- 1999 - 2005 Assistant Professor, Interdisciplinary Exercise Science Ph.D., ASU
- 1998 - 2005 Assistant Professor, Department of Kinesiology, ASU
- 1998 - 1999 Supporting Faculty, *Adaptive and Computational Aspects of Motor Coordination*, Flinn Foundation, Motor Control Laboratory, ASU
- 1996 - 1998 Researcher, *The Development of Bimanual Coordination*, Purdue Research Foundation, Purdue University
- 1993 - 1996 Research Assistant, *Prosodic Elements of American Sign Language* (Anne Smith, PI, and Howard Zelaznik Co-PI, National Institute of Health, NIDCD). Purdue University.
- 1993, Feb. Research Assistant, Quebec-Ontario researcher exchange grant, University of Montreal.
- 1991 - 1993 Teaching Assistant, McMaster University.
- 06 - 08, 1989-1991 Instructor, McMaster Sport Fitness School

Honors and Awards:

2015	Excellence in Research Award	NASPSA
2014	Apple Polisher Award	Devils Advocates ASU
2014	Super Mentor	BUILDing SCHOLARS Grant
2012	Outstanding Professor Award	Order of Omega
2011	Nominated for Professor of the Year	ASU Parents Association
2010	Nominated for teaching award	CLAS, ASU
2009	Special Recognition for Professor of the Year	ASU
2008	Featured as Arizona's Leading Women Scientists	Phoenix Woman Magazine
2006	Research Career Award	World Down Syndrome Congress
2005	Early Career Distinguished Scholar (nomination)	NASPSA
2003 - 2004	ASASU Centennial Professor (see internal grants)	Arizona State University
1997 - 1998	Outstanding Graduate Student in Scholarship/Service	Purdue University
1995 - 1996	Young Scientist Award	SCAPPS
1988 - 1991	Dean's Honor List	McMaster University
1991 - 1992	Centennial Entrance Scholarship	McMaster University
1991 - 1992	McMaster Graduate Scholarship	McMaster University
1989 - 1990	University Scholarship	McMaster University
1987 - 1988	McMaster Entrance Scholarship	McMaster University
1985 - 1986	Public Speaking University Entrance Scholarship	Optimist International

ABSTRACT

Down syndrome (DS), well known as trisomy 21, occurs in one in one out of 700-1000 live births in all ethnic groups. DS is a very common cause of mental impairment and children with DS present with a variety of medical issues, including cardiovascular defects, endocrine problems, neurodevelopment disorders, hematological problems, gastrointestinal and sleep dysfunctions, visual and hearing impairment. It is well known that there is an association between DS and autoimmune disorders. Thyroid dysfunction (mostly autoimmune hypothyroidism) is the most typical endocrine disorder in individuals with this syndrome (affecting 0 to 66% of these patients). In these patients, in contrast with the general population, there are not substantial differences of incidence between sexes. It can be either congenital or acquired, and usually presents as a subclinical disorder. Hyperthyroidism as well is more commonly seen in people with DS than in the general population, and the phenotypic metamorphosis from hypothyroidism to hyperthyroidism is more frequently seen. Moreover it is described in the literature an increased frequency of shortness of stature, diabetes mellitus, and nutritional disorders (overweight and obesity) in children with DS. An increased oxidative stress, probably due to the over expression of the gene for Cu/Zn superoxide dismutase (*SOD1*) located in chromosome 21, is observed in DS people and this fact may play a role in the higher prevalence and severity of a number of clinical conditions linked with the syndrome, as well as the accelerated ageing observed in these individuals. An endocrine follow up is required for these individuals, in order to early detect any subclinical abnormalities and prevent as many consequences as possible.

INTRODUCTION

Down syndrome (DS; OMIM #190685) is a chronic and complex medical condition affecting multiple systems that exhibits a prevalence of 1 in 700 live births and results from an extra 21 chromosome or a duplication of a critical portion of this chromosome [1].

Subjects with DS show distinct physical and facial features such as round face, slanting palpebral fissures with flat nasal bridge and epicanthic fold, short broad hand, hypotonia, simian palmar crease, low set ears, a wide gap between 1st and 2nd toes, a prominent neck fat pad, and a protruding tongue [2]. However, these subjects have a high prevalence of congenital heart disease, neurodevelopment issues and presenile dementia, hematological problems until to leukemia, gastrointestinal and sleep dysfunctions, dislocation of cervical vertebrae and are at higher risk for developing disorders such as hypothyroidism, hearing and visual impairment, obesity, diabetes, precocious puberty, dyslipidemia and bone impairment [3]. Moreover the association between DS and autoimmune endocrinopathies is well studied. These disorders become increasingly frequent as children grow up, particularly during adolescence, and the onset of one is often followed by the development of others [4, 5].

The purpose of this chapter is to evaluate retrospectively the data of auxological and endocrinological parameters in patients with this genetic disorder. Relevant papers have been identified through systematic searches of the Pubmed, EMBASE and Cochrane databases. All published studies in the English and non English language concerning this disorder have been identified. Keywords in the literature search have been entered in all combinations. Searches included manually reviewing the reference lists of all original articles and all systematic review articles, with each study being evaluated for inclusion.

LENGTH, HEIGHT AND GROWTH HORMONE AXIS

DS is notoriously correlated to postnatal growth deficiency that finally leads to short stature [6]. In particular, growth velocity is most reduced between 6-9 months and 3 years of age but subsequently is almost normal [7]. However, the average length and height in prepubertal DS is around the 2nd centile in growth charts for the general population [8].

In this syndrome, the causes of this growth retardation are not known in most patients [9]. However, the main conditions participating to the poor growth are congenital heart diseases [10, 11], thyroid diseases [5, 12, 13], celiac disease [5, 14], pubertal disorders [15], feeding problems [16], and sleep related upper airway obstruction [17].

Many countries elaborated their own specific growth charts for DS [7, 18-22]. For instance, in Sweden specific growth charts were created and they found that mean birth length was 48 cm in both sexes in DS, and mean birth weight was 3.0 kg for boys and 2.9 kg for girls [20]. According to this study, final height in individuals with DS was precociously reached at 16 and 15 years for males and females, and the mean height was 161.5 cm and 147.5 cm respectively [20]. Head growth was impaired, resulting in -0,5 SDS for head circumference (Swedish standard) at birth, decreasing to -2.0 at 4 years of age [20]. Puberty tends to start early and the charts revealed a decreased pubertal growth rate in DS [20]. Interestingly European DS boys are taller than corresponding Americans, whereas European DS girls, although being lighter, have similar height to corresponding American girls [20].

Similarly Al Husain et al. [19] reported growth charts for DS Saudi children less than 5 years of age. Their data confirmed the impaired growth at most ages, showing a high proportion of underweight children with DS in the first two years of life, with a tendency to gain weight, also excessively, by the age of 3 years; half of the children with DS had a head circumference below -2 SD for age and sex [19].

A Dutch study, retrospectively evaluating the growth data in a DS population, demonstrated that there are three age periods when height differences between children with and without DS are particularly relevant: during pregnancy, during the first three years of life, and during puberty [23]. Based on these references health care professionals can focus on the critical age periods and provide an accurate follow up to optimize growth [23].

Regarding the short stature, many studies were conducted to understand the underlying causes in DS, and in particular if growth hormone (GH) deficiency may play a role in growth retardation in these patients [24].

For instance Castells et al. evaluated GH secretion through levodopa and/or clonidine stimulation tests and GH secretory patterns by the integrated 24 h, founding out that DS children present a reduced serum GH response to GH stimulation tests, or disparity in responses to the stimulatory tests and a low GH concentrations in 24 hours [25]. For this author, the data suggest that GH deficiency (GHD) may be implied in growth failure in patients with DS and that hypothalamic dysfunction may be the primary cause for GHD in this syndrome, as reported by the blunted response to levodopa and clonidine tests and the normal results after growth hormone releasing hormone (GHRH) plus arginine test [26].

However, not all of the studies agree with these results. In fact, Pueschel et al. [27] found that the response of GH secretion varies depending on different stimulation tests. In this study, all children tested were able to secrete normally GH ($> \text{or} = 10 \text{ ng/ml}$) at least during one of the tests performed, affirming that GH secretion was significantly lower if compared with levels in normal children only after clonidine administration [27]. This data may support the hypothesis that children with DS present a decreased GH secretion and, consequently, a reduced linear growth [27].

Anyway, with the strong suggestion that an inappropriate GH secretion may be implicated in growth retardation in DS, it was suggested to evaluate the effect of a recombinant human growth hormone (r-hGH) treatment. However, there is a big concern about safety, being GH therapy contraindicated in people prone to cancer development like children with DS.

For this reason many studies about GH therapy were conducted in the past, but nowadays they have a role especially in the study of mechanisms involved in growth retardation. In these regards, many data suggested that height and growth velocity improved after one year or more of r-hGH treatment. The benefits of GH therapy do not stop here, since r-hGH may result in a significant increase in the mean head circumference standard deviation score (SDS) at 12 months in these patients [28]. Bone age may increase during the first year of treatment, resulting correspondent with chronologic age. No significant side effects were recorded, but the long term risk of cancer should be taken into consideration [28].

Meguri et al. [24] confirmed the growth-promoting effects and safety of GH treatment in children with DS and GHD. In fact, in presence of GHD, short stature benefit from 3 years treatment with r-hGH, as the height SDS increased from -3.5 at start to -2.5 after three years of r-hGH treatment. In these patients, no new safety concerns were observed [24].

Moving on to effects of GH therapy besides linear growth, it was postulate that insulin-like growth factor I (IGF-I) may be involved in brain development, in addition to the well known

effect on stature [29]. On this hypothesis, Annerén et al. [6] aimed to study the long term effects of r-hGH on linear growth and learning disability in young children with DS. Fifteen children with DS aged 6 to 9 months were treated with GH for three years. Results were encouraging, since the mean height of the study group increased from -1.8 to -0.8 SDS (Swedish standard) during treatment, whereas that of an untreated DS control group decreased from -1.7 to -2.2 SDS [6]. Concentrations of serum IGF-I and IGFBP-3 became normal during GH treatment. Growth velocity declined after treatment stopped [6]. However no significant differences in head circumference were recorded during treatment, neither in psychomotor development [6].

In conclusion we can assert that growth in children with DS is notably different from that of healthy children. For that reason, the use of DS specific growth charts to properly evaluate and compare the growth of these children is highly recommended. In DS children suffering from a growth deficiency associated with a GH deficiency, even if GH therapy is not strongly recommended in these patients, this treatment appears to be efficacious and sure.

WEIGHT AND NUTRITIONAL HABITS

In the first years of life many patients with DS may show a failure to thrive [30]. The reasons of this fact are multiple, for exemple DS children present a remarkable rate of gastrointestinal tract abnormalities (noted in until 12%) most commonly consisting of duodenal atresia, Hirschprung disease, trachea-esophageal fistula, pyloric stenosis, annular pancreas and anal/rectal atresia [31, 32]. A dysfunctional gastrointestinal tract can cause an incorrect absorption of nutrients. Furthermore the gastrointestinal defects that are frequently discovered in these patients also bear responsibility for nutritional deficiencies, constipation and slow intestinal peristalsis, that are common findings in DS children and adolescents [16, 33]. Some DS children exhibit feeding difficulties in chewing and swallowing food and they prefer consuming foodstuffs made of a lower intake of fresh fruit and vegetables, and increased intake of simple carbohydrates that are easy to chew and swallow [16]. We need to consider also that inappropriate choices of foodstuffs on the basis only of children's tastes are commonly taken. Also this fact contributes to various nutritional deficiencies and a lack of regulating dietary ingredients as well as low dietary fiber intakes [16].

Finally, as causes of failure to thrive in DS there may be also dental features such as delayed or atypical tooth eruptions, agenesis, malocclusion, tooth decay and periodontal disease, that are frequent findings in these patients [34, 35].

Moreover, as well as other children and adolescents with intellectual impairment, DS patients are at increased risk for metabolic disorders and in particular overweight or obesity [36]. However, the prevalence of overweight and obesity in individuals with DS varies in literature. In a Dutch study of 1596 individuals with DS aged 0–26 years, the prevalence of overweight and obesity was reported as 25.5% and 4.2% for men and 32% and 5.1% for women, respectively [37]. In the USA, Rimmer et al. [38], in a sample of 81 DS adolescents (aged 12–18 years), found that 55% was overweight and 31.2% was obese. However, in another, retrospective, study from the USA, involving 283 adolescents and adults with DS, the authors reported a 56% prevalence of overweight for women and 45% for men, over 36% and 33% respectively in the general population [39].

There are many factors that are known to influence obesity in DS, both metabolic and environmental. They range from thyroid dysfunction and decreased basal metabolic rate, along

with hypercholesterolemia, increased leptin levels and deficiencies of vitamins and minerals to low levels of physical activities [40].

Hyperphagia as well seems to play a role in these children. Hyperphagia is known to have a primary role in Prader Willi Syndrome (PWS), but it has not been well investigated in DS. This is the reason why Foerste et al. [41] analyzed this symptom through questionnaires proposed to 52 young people aged 6–18 years, equally classified in DS (17 patients), PWS (16 patients) and lifestyle-related obesity (LRO: 19 patients). As hypothesized, the PWS group scored high levels of hyperphagia and the LRO group had the lowest, but it was pointed out that DS group presented food-seeking behaviour more pronounced than in the LRO group and the latter spent more hours per week engaged in physical activity [41].

There is a metabolic predisposition to overweight that is objective, and, unfortunately, less easy to control. Interestingly, DS patients show high leptin levels, a hormone that regulates hunger and satiety and appetite [16].

However children and adolescents with DS have been shown to take part in less vigorous physical activity and had higher BMI levels compared with their siblings [42–45]. The basis of this may be medical conditions such as cardiac issues and precocious fatigability but also unawareness or unavailability of adequate gym programmes within the community. Moreover practicing sport and activities out of a familiar contest may constitute another hindrance to physical activity for these fragile individuals, in which unwillingness of practicing sport may play an important role [46–48]. Lack of physical activity may be a major contributor to the development of overweight within the DS population, but what is important is that it is, differently from others, a preventable risk factor.

Another factor that can affect DS subjects is tendency to depression and anxiety that significantly affects the relationship with food, such as making inappropriate food choices, tasting and hyperphagia or compulsive eating, and this aspect may become more evident during adolescence. It would be worthwhile to provide further education for families with a DS child to inform about the risks of over-eating, especially in the contest of primary care, and to be included in a health policy in which local dieticians may participate to sustain exercise programmes and physical activity in patients with intellectual disabilities [16, 41].

Finally, many studies demonstrated reduced dietary intakes of fiber and some vitamins and minerals in DS subjects (in particular vitamins A, B and C along with calcium and zinc) [16]. DS children showed deficiencies in the B vitamins group (i.e., B1, B2, B6, B12 and folic acid), which are implicated in intellectual development, notoriously inadequate in DS children. Vitamin B1 deficiency causes weakness, constipation and decreased mobility, whereas B2 deficiency results in mucocutaneous alterations. Vitamin B6 deficiency gives rise to mental retardation and a lack of concentration. Deficiencies of vitamins B6, B12 and folic acid are linked to abnormal levels of homocysteine in the bloodstream of DS children [16].

We conclude assessing that prevalence of obesity and overweight in patients with DS is increased compared to general population and there we strongly underline the need for a health policy and education about appropriate nutritional behavior for individuals with intellectual disability to prevent sedentary activity and the burden of overweight and obesity.

PUBERTY AND FERTILITY

In patients with DS, puberty starts in a range of age similar to that of the general population. Anyway there are several case reports of a syndrome, called Van Wyk and Grumbach syndrome, that includes precocious puberty in children who were also identified to suffer from hypothyroidism, and many case reports of DS children with this syndrome have been reported in literature, providing evidence for a linkage between these two conditions [15, 49].

Van Wyk and Grumbach syndrome was first reported in 1905 by Kendle, who described the case of a 9-year-old girl with menarche at age 5, fully developed breasts, and the clinical symptoms of primary hypothyroidism, who fully recovered after treatment with thyroid extract (in particular her growth moved on, her menstruation stopped, and her symptoms of cretinism resolved) [50]. However, in 1960 Van Wyk and Grumbach well analyzed this syndrome, that is a condition consisting of primary hypothyroidism, precocious puberty, and solitary or multiple ovarian cysts which can become massive in certain cases [51].

The review of the literature reveals that the majority of these patients have bilateral rather than unilateral masses [15, 49]. Sexual precocity usually is associated with increase in linear height, acceleration of bone maturity and epiphyseal fusion, which finally leads to short stature. On the contrary, a long standing, untreated, primary hypothyroidism has classically been associated with retardation of linear growth and delayed puberty. Differently, in the patients with Van Wyk and Grumbach syndrome, untreated hypothyroidism leads to growth delay, delayed skeletal maturation, and precocious puberty, in presence of a retardation of bone age [15, 49]. This syndrome occurs both in boys and girls. In these patients, there is usually pituitary enlargement, demonstrable on computerized tomography (CT) scan or MRI and this fact could mislead to the case of a pituitary tumor. Pituitary hyperplasia may be identified and is probably due to long standing thyrotrope stimulation in response to the decreased thyroid hormone [15, 49].

Girls present with early thelarche, enlarged labia minora, and estrogenic changes in vaginal smear, with or without appearance of pubic hair [52]. There may be irregular vaginal bleeding and solitary or multiple ovarian cysts. Serum prolactin, follicular stimulating hormone (FSH), levels are elevated and luteinizing hormone (LH) levels are low or normal [53]. A similar precocity is known to occur, even if less frequently, in males as well. Boys present with enlargement of the testes because of increase in size of the seminiferous tubules, hence as a direct effect of hypothyroidism on the prepubertal testes leading to over proliferation of Sertoli cells. Signs of virilization and Leydig cell maturation are absent. Plasma testosterone concentration is prepubertal [54].

An explanation of this syndrome could be that the low levels of T_3 and T_4 hormones caused by primary hypothyroidism elicit a TRH secretion, that cause an increase in TSH levels, prolactin, LH and FSH. However, further explanation are required for sexual precocity in primary hypothyroidism, as in uncomplicated juvenile hypothyroidism puberty development is usually delayed. Interestingly, in these patients the FSH level is elevated, LH level is either low or normal. The increased FSH release and high FSH/LH ratio is thought to cause the increased ovarian estrogen secretion in girls and this is different from normal puberty, where LH raises to higher levels and the LH/FSH ratio is high. However, a more accepted theory is the fact that TSH can act on the FSH receptor. TSH, FSH, LH and hCG, share a common beta subunit. It is believed that large amounts of TSH can activate the FSH receptor due to the presence of this

common subunit. Gordon et al. demonstrated that the elevated estrogen levels seen in this disorder come directly from the ovaries, being the patient's serum estradiol level significantly lower than estradiol directly aspirated from the ovary [55].

Regarding the fertility, it is unclear whether people with DS can be considered infertile. There have been cases of males and females with this syndrome that successfully reproduced. In males, FSH and LH levels are normal during the beginning phase of puberty, but are elevated post puberty. The levels of testosterone appear normal throughout puberty. The size of penile length and the size of the testis in DS people are below the average, suggesting a partial gonadal deficiency leading to infertility. In females normal reproductive organs have been observed and there are not abnormalities in both external genitalia. Females usually have regular menstrual cycles. FSH and LH hormone levels are in normal range potentially leading to successful reproduction. Another explanation for the infertility in people with Trisomy 21 could be the lack of knowledge about sexual intercourse, that may contribute in patients there often do not have objective problems to their reproductive system [56].

THYROID FUNCTION AND DISORDERS

These are just few examples where a genetic syndrome and thyroid disorders show a close links as that in DS. In fact for a long time many researchers thought that DS was due to a kind of thyroid disease (TD). In 1866 John Langdon Haydon Down (1828-1896), superintendent of the Earlswood Asylum for Idiots in Surrey (England), made his contribution by differentiating children with cretinism due to congenital hypothyroidism (CH) from children with DS already [57], however in 1896 Telford Smith noted the resemblances between DS and CH, theorizing that they were two aspects of the same problem (Table 1) [58].

However, the clinical resemblance between the two patient groups may make difficult to detect developing TD in children or adults with DS [59]. For this reason optimal care in DS requires close follow-up and early intervention to minimize disease and dysfunction related to TD [3]. Moreover, in the 1970s, individuals who lived longer than 45 were rare, however, today over half the individuals born with DS live into their 50's, 40% of them into their 60's and 13% to the age of 68 [60].

In fact, hypothyroidism can affect a child with DS at any age [61] and is sporadically detected by routine neonatal thyroid screening [61]. Thus, the annual preventive medical protocols for individuals with DS of all ages always should include a blood test for TD [59].

Clinical forms of hypothyroidism found in people with DS include transient and primary hypothyroidism, pituitary-hypothalamic hypothyroidism, chronic lymphocytic thyroiditis (Hashimoto's thyroiditis, HT), and autoimmune hyperthyroidism (Graves' disease, GD) [62].

Many data suggest that the percentage of individuals with DS at risk for TD gradually increases with age. At birth 0.7% of the infants with DS have persistent primary CH [63] whereas the rate of adults with hypothyroidism rises to at least 12% [64].

Table 1. Comparison of physical characteristics of subjects with Down syndrome and hypothyroidism

Characteristic	Down syndrome	Hypothyroidism
Appearance	Dull, chubby	Dull, chubby
Head	Microcephalic	Normal
Tongue	Large	Large
Nasal Bridge	Underdeveloped	Underdeveloped
Eyes	Slanted	Not slanted
Neck	Short	Short
Heart	Murmur (AV canal)	Murmur (thick valve and septum)
Abdomen	Protuberant umbilical hernia	Protuberant umbilical hernia
Neuromuscular	Hypotonia	Hypotonia
Skin	Dry	Dry
Extremities	Short, transverse palmar crease	Short, no transverse

Adapted by [58].

Congenital Hypothyroidism (CH)

CH due to athyreosis has been occasionally described in infants with DS [65, 66]. The incidence of persistent primary CH in infants with DS is 1:141 (28 times more frequent) compared to 1:3800 in the general population [63]. Cutler et al. studied 49 DS children less than three years of age and found that 6% had CH [67]. He noted also that 27% of them already had mildly increased TSH levels [67]. In many patients, in fact, the neonatal hypothyroidism is transient and follow-up is always needed [63, 68]. In fact, DS patients are more likely to have iodine exposure in the neonatal period as a result of cardiac surgery and gastrointestinal contrast studies, potentially causing transient TSH elevation (Wolff–Chaikoff effect) [69].

The exact reason of the high incidence of hypothyroidism in neonates with DS is not fully understood. In the past several data suggested that there is an increased incidence of TD in mothers of DS newborns [70]. However, other studies did not find a consistent increase in the prevalence of thyroid antibodies in their mothers [71].

Recent data seem to suggest that in DS children we observe an idiopathic mild plasma TSH elevation (4–10 mIU/l), up to 100%, during their first 6 months of life, that decreases with age [72], and that DS patients have T₄ levels substantially decreased compared to the general newborn population [72]. The clinical significance of this dysfunction is not well known. The existence of a mild hypothyroid state in DS newborns supports the hypothesis of the presence of a DS-specific thyroid function's regulation [72]. It is important to note that, without appropriate treatment, hypothyroidism leads to relevant developmental delay [60]. However van Trotsenburg et al. [73] has demonstrated that L-T₄ treatment in DS newborn may improve growth and neurological development in the first 2 years of age.

Finally, it is interesting that, as in CH patients, both DS with CH and subclinical hypothyroidism showed a significantly higher presence of gastrointestinal malformations [74], focusing on the importance of organizing a particular follow-up for DS presenting gastrointestinal anomalies and CH.

Hypothyroidism

This thyroid dysfunction, represented commonly by HT, is the most typical endocrine abnormality in patients with DS. The estimated lifetime prevalence rate of thyroid dysfunction in DS varied widely in different studies, depending on variations in population size, age, laboratory assays and definitions of thyroid dysfunction used. This is why the rate of thyroid dysfunction ranged from 30% to 93% of cases of hypothyroidism [75]. During childhood, the problem of diagnosis of hypothyroidism by clinical criteria alone remains a difficult one [59]. The importance of annual preventative medical blood testing cannot be overstated [59]. Moreover, thyroid function assessment must be carried out periodically, annually after the first year of age [3, 76]. By the time that the prominent features of severe hypothyroidism (growth deviation from a previous channel of growth, plateauing of intellectual growth, increased lethargy, constipation and eventually the development of myxedema) are seen in the patient, DS children may already have major adverse effects of the disease process [58], such as myxedema coma [77], vaginal bleeding [49], obstructive sleep apnoea [17], or pericardial effusion [78].

Goitre, which can be seen with hypothyroidism, hyperthyroidism or even euthyroidism is one of the more obvious clinical clues [79].

The first case of DS with HT was reported by Benda [80]. In 1985, Pueschel and Pezzullo reported the thyroid function of 151 children with DS and their sibling controls [81]. In this series, 27% had an abnormality of TSH, T₄ or both. They noted that there were higher TSH concentrations in adolescents and decreasing T₄ levels with the advancing age of the patients [81]. These authors also raised the question of whether the decline of intelligence quotients described in the literature over time in people with DS might be, in part, due to inadequate thyroid function [81]. However, another study has found no differences in intelligence quotients between children with and without elevated TSH [82].

Loudon et al. published a series of 116 home-based children, discovering three hypothyroid, one hyperthyroid and 29% with thyroid antibodies [83]. The authors noted that transient increases in TSH levels seemed common in these children, particularly during periods of intercurrent illness [83].

In 1991, Pueschel updated his series to 181 patients and found 6% of children had both high TSH and low T₄ [84]. In 1993, a five year longitudinal study was published of 101 children with a mean age of five years and three months [82].

Thyroid auto antibodies are also frequently positive, and Hashimoto's thyroiditis is the most common cause of hypothyroidism in DS. The risk of progression appears to be similar to non-DS patients [69]. DS patients may be incline to manifest over time a phenotypic metamorphosis from HT to GD and to subsequently fluctuate from hyperthyroidism to hypothyroidism [13].

The frequency of antithyroid antibodies (ATA) among patients with DS and hypothyroidism increases with age. ATA associated with hypothyroidism are significantly less common in DS children under 8–10 years of age. However, some studies reported ATA-positive DS children under 3 years of age [85, 86]. Several studies observed a much higher prevalence of thyroid disorders in children with DS and Type 1 Diabetes (T1DM) than that usually described in DS without diabetes [87, 88]. This fact therefore suggests that the subgroup of trisomic patients with T1DM carries an even higher risk of aggressive autoimmune disease.

Zinc deficiency, which appears to be more common in DS children, can affect endocrine and immunological function. Normalisation of serum zinc and TSH was reported in DS patients following 4 months of oral zinc in a non-randomised study and this was later replicated [89]. Conversely, a subsequent study found no difference in thyroid function between DS patients who were zinc deficient and those who were depleted [90].

Approximately 40% of children with DS have congenital heart disease. Some studies of adults with subclinical hypothyroidism (SH) showed abnormalities of myocardial function, reversible with L-thyroxine treatment [91]. A small study of 16 DS children with prolonged SH, showed no difference in myocardial function compared to age and body-surface area matched euthyroid DS controls [92].

In Table 2 we reported some of the more significative studies regarding thyroid function in DS.

During the course of the study, in addition to the three children who entered the study with abnormal thyroid tests, eight more children developed elevated TSH, in all cases with normal T₄ and T₃ tests [82]. Only one of these eight then further developed uncompensated hypothyroidism; this patient had thyroglobulin and microsomal thyroid antibodies [82].

Mildly elevated plasma thyrotropin concentrations in the absence of signs of thyroid autoimmunity are also common [116]. There is little knowledge about the reason of this phenomenon and it is a common therapeutic dilemma. Konings et al. reported the presence of a normal bioactivity of TSH in DS [116]. Other authors have suggested that reduced thyroid function in patients with DS may be linked in some way to the low serum levels of selenium found in these patients [117].

Moreover, autoimmune thyroid disease (ATD) is very uncommon in young children, but has been recognised in association with DS [118]. The pathogenesis of autoimmune thyroid disease is complex and, to date, there is no single unifying hypothesis to explain the changes in immune function and the increased incidence of ATD in patients with DS [119]. There is an interest in the possible effects of over expression of proteins whose genes are encoded on chromosome 21 and which participate in the regulation of the immune response [119]. Increased expression of chromosome 21 gene products may be directly responsible for altered immune function and predisposition to autoimmune disease [118].

The increased frequency of thyroid dysfunction and the mild presentation of hypothyroidism in DS can be responsible of unjustified medically treatment of thyroid diseases in these patients [120]. However, other data seem suggest a low adherence to national guidelines for thyroid screening [121].

The risk of thyroid dysfunction increases with age in patients with DS [94]. In a study conducted in 1990 that involved 106 adults from 20 to 67 years of age (with an average age of 38 years), 40% had blood test that revealed an abnormal thyroid function. However, it should be noted that not all patients with abnormal test results had an active disease process: only seven had active hypothyroidism and one had thyrotoxicosis [104].

Hyperthyroidism. While hypothyroidism is the most frequent alteration in DS patients, we must consider that hyperthyroidism as well does occur in DS [110]. In fact, the incidence of thyrotoxicosis in DS patients exceeds that in the general paediatric population, which varies from around 0.1:100,000 in childhood to 3:100,000 in adolescence [75]. After the first described case of thyrotoxicosis in a 22 yrs. old DS female in 1946 [122], many case reports were published in the literature reporting hyperthyroidism in DS [67, 83]. Before the study of Goday-Arno et al., [123], a total of 46 cases of hyperthyroidism have been previously reported

in DS [123]. The more significant data of prevalence of hyperthyroidism are reported in Table 2.

Hyperthyroidism associated with DS can occur as a result of an autoimmune diffuse enlargement of the thyroid gland (GD) rather than the presence of a toxic adenoma or toxic multinodular goiter. However, exophthalmos appears to be less frequent [110].

In children with DS, clinical recognition of hyperthyroidism can be difficult because symptoms may be hidden [124]. The shortness and chubbiness of the neck makes it more difficult to detect thyromegaly, so a careful palpation is necessary [110, 123].

In DS, suggestive findings of hyperthyroidism also include weight loss, hyperactivity, diarrhoea, nervousness and goitre. The thyroid examination revealed frequently diffuse thyroid enlargement in all patients. All patients had undetectable serum TSH concentrations with elevated serum FT₄ concentrations and elevated serum total T₃ concentrations. Thyroid antibodies were present in 11 of 12 patients (92%). A thyroid scan showed diffuse thyroid uptake in all patients, which was suggestive of GD.

At the present time, there is no clear consensus on the best way to treat hyperthyroidism in children with DS and in most of the cases described details of the therapy were frequently unclear [123]. However, there are three possible treatments of hyperthyroidism. One treatment is aimed at blocking the action of the TH on body tissues. This involves the use of antithyroid drugs, and are often the first treatment used [123]. However, almost all of these drugs can cause significant side effects.

A second treatment is surgery to remove part or the entire thyroid; and then the child or adult should use drugs for thyroid replacement. The third treatment is the use of radioactive iodine, which destroys the thyroid's ability to produce thyroid hormone. The patient then takes replacement thyroid hormone. However, radioactive iodine treatment is not often used in children because of the risk of thyroid cancer.

Thyroid cancer. In literature we found only one benign neoplasm, an oncocytic adenoma [124] and four thyroid cancers: an unspecified cancer, one papillary and one follicular carcinoma [125-127], and one thyroid lymphoma [128].

So, although thyroid disorders such as thyroiditis and goiter, decreased serum selenium, celiac disease, and high body mass index, are all factors potentially favouring an enhanced risk of thyroid cancers, this entity seems to be exceptionally reported in DS, such as confirmed also by the Oxford Record Linkage Study about the data of 1453 individuals with DS [129]. However, thyroid neoplasm appears at a younger age than other carcinomas and life expectancy has greatly improved in people with DS [129]. Finally, it is particularly important to underline that thyroid nodules are rarely reported in people with DS [125].

The review of the literature showed that thyroid neoplasm are under-represented in DS. Moreover a particular distribution of histological types of cancer in DS was observed, where carcinomas are under-represented and lymphomas are more frequent [125, 129].

In conclusion, thyroid diseases (with the exception of thyroid cancer) occur with greater frequency in individuals with DS than in control populations. These patients are at risk from infancy throughout adult life. Therefore, follow-up of growth patterns, searching clinical signs of diabetes, thyroid function monitoring, screening for thyroid auto antibodies and measurement of serum concentrations of antiigliadin and antiendomysium self-antibodies should be started from infancy to prevent further deterioration of growth and mental development. Interpretation of thyroid test results always should be made by a specialist who is aware that elevated TSH levels sometimes are transient in DS.

BONE MINERAL STATUS AND METABOLISM

Among all the disorders described in DS patients, there is also impairment of bone metabolism. DS children are notoriously prone to develop osteoporosis, bone fragility, and related fractures and their vitamin D levels are usually lower than in the general population.

Since life expectancy of DS patients significantly raised, it is important to let them reach a good value of peak bone mass to prevent osteoporosis and bone disorders during the elderly [130]. Several studies have reported that DS patients have a lower level of bone mass than people without DS, but the reason of this disorder remains still unclear. Lifestyle factors like alimentary choices and physical activities may play an important role, but further information need to be gathered whether or not specific effects of chromosome 21 genes are also implied [131, 132].

González-Agüero et al. affirmed that DS subjects have a clear tendency to reach lower bone mass density (BMD) in several regions of their bodies also in pediatric age when compared with age and sex-matched subjects without DS. Furthermore they provided evidence that young females with DS are poorer at acquiring bone mass than young males with DS [133]. 30 patients with DS were examined by McKelvey et al. using dual-energy X-ray absorptiometry (DXA) to measure BMD, revealing that 53.3% showed a BMD ≤ -2 SDS. The authors also demonstrated that both bone formation and reabsorption were suppressed in DS compared with controls, indicating low bone formation and decreased bone turnover as the primary causes of the low bone mass observed in these patients [132]. A similar work was performed by Wu, who analyzed BMD by DXA between preadolescent boys with and without DS and confirmed that patients with DS have lower BMD and bone mineral content (BMC), also localizing in the pelvis the first site to show bone impairment in DS [134]. These results were partially confirmed by peripheral Quantitative Computed Tomography (pQCT), which is another instrument that provides information about volumetric bone mineral density (vBMD). BMD was found to be higher in determined skeletal sites in DS children according to González-Agüero et al., even if they have a higher risk of suffering bone fractures due to a decreased bone resistance to load bending or torsion [135].

Many factors are thought to be related to bone disorders in DS, from hypotonia, that is a well-established characteristic of DS and may limit physical activity, to low amounts of physical activity indeed, or poor calcium and vitamin D intake due to alimentary choices and malabsorption, celiac disease, and hormonal factors [75, 136].

It is believed that the combination of all the risk factors is the cause of bone alterations in DS. In fact neither the increase of physical activity alone, nor the increase of calcium intake alone, demonstrated a significant effect on BMD. Then authors observed patients with DS who received a higher calcium intake and, at the same time, who were subjected to a specific program of physical activity, and found that these subjects showed a benefit in terms of BMD from both the intervention together [137]. Another aspect that needs to be considered are lower levels of vitamin D in the bloodstream reported in DS, particularly in subjects with obesity and autoimmune diseases, as demonstrated by Stagi et al. in a longitudinal study. In the same study parathyroid hormone levels were found to be significantly higher in DS subjects compared to controls and cholecalciferol supplementation improved levels of 25(OH)D levels even if the progress was less remarkable than that observed in controls. This is the reason why it would be worthwhile to give DS patients with obesity and autoimmune diseases higher cholecalciferol

supplementation [138]. Physical activity has a well-known effect on reducing the risk of developing future bone fragility, fractures and osteoporosis, as proved in a study in which adolescents with DS who spent more time practicing sport, had a higher BMD Z-score at the hip, and therefore less risk for osteoporosis [136]. Ferry et al. demonstrated that physical activity produces different effects in some skeletal segments compared to others. In fact one year of training increased bone mineral content at lumbar spine and total hip, but influenced BMD only at lumbar spine when measured with dual X-ray absorptiometry (DXA). Moreover there was no evidence of bone improvement when the bone tissue of the same individuals was analyzed with ultrasound techniques. In Down syndrome bone is able to adapt to mechanical stimulation even if the responsiveness seems to be reduced than that currently reported in the literature for normal individuals [139]. Thus DS are prone to osteoporosis, impaired bone mass and fragile bones. Many factors prevent correct bone turnover and gain in DS, either preventable or not. Therefore it is required a multidisciplinary approach that includes programmes to promote physical activity, an optimal calcium and vitamin D intake and periodic endocrine evaluations of bone mineral density [140].

AUTOIMMUNE DISEASES

DS patients present several immunological disorders, a high rate of infections, cancer and autoimmunity, and there is a well recognized association of DS with autoimmune diseases, in particular, thyroid disorders, type 1 diabetes and celiac disease [141]. Da Rosa Uttyama et al. investigated the prevalence of auto antibodies of various types (such as anti-mitochondrial, smooth-muscle, liver-kidney microsomal, nuclear, gastric parietal cell and neutrophil cytoplasmic antibodies and rheumatoid factor) in 150 Caucasoid DS children and adolescents and 105 healthy children, finding that 28.6% of DS patient revealed positivity to at least one autoantibody in comparison with 8% of the controls. RF was frequently detected (28% of the patients and 6.7% of the controls), even if nobody showed clinical evidence of rheumatic disease, so that the meaning of this finding remains unclear, being hypothesized either an expression of deregulation of immune system or an earlier marker of rheumatic diseases in these patients [142].

Thyroid autoimmunity is a notorious possible finding in DS, as previously seen, but also celiac disease, type 1 diabetes and other autoimmune disorders are common to observe. Autoimmunity in particular is very frequent in DS, especially if compared with other genetic disorders like Williams-Beuren Syndrome [5].

At the root of the tendency to develop autoimmunity in these patients there is an immunological disorder, that some studies attribute to a dysregulation of autoimmune regulator protein (AIRE), a transcription factor located on chromosome 21, that plays a crucial role in autoimmunity by regulating promiscuous gene expression (pGE). In DS individuals in fact AIRE expression is significantly reduced in thymuses compared with controls and decreased expression of AIRE was found to be accompanied by a reduction of pGE [143]. In these subjects the ability to proliferate of DS T cells doesn't seem to be altered significantly, however there is an over expression of T (reg) population that, in spite of this, show a reduced inhibitory potential compared to healthy controls. The defective inhibitory activity may partially explain itself the higher frequency of autoimmune diseases [144]. Another difference in DS children is

that the thymus was found to be smaller and with an abnormal structure since birth in DS subjects. Hypergammaglobulinaemia of immunoglobulin IgG and IgA after the age of 5 years, with high levels of IgG1 and IgG3 and low levels of IgG2 and IgG4, may be present in DS. In DS subjects both B and T lymphocytopenia (that concerns CD4⁺ helper as well as CD8⁺ cytotoxic T lymphocytes) is very frequent in DS, and the physiological expansion during the first year of life is not observed, suggesting an abnormal reaction to antigenic stimulation [145-147].

CONCLUSION

Our study aimed to focus on the major endocrine problems that a DS patient may suffer from. It is well known that DS children are prone to develop thyroid disorders, mainly hypothyroidism, but also pubertal disorders, overweight and obesity, as well as short stature and low bone mineral density are conditions that we frequently observe in DS individuals. The average life expectancy of children with DS considerably increased over the past few years. This is a sign that health care professionals learnt how to deal with their problems and harmonised the required treatment. At the same time this fact implies that we have to take into consideration also long term consequences of medical issues that might come up. Finally we conclude assessing the importance of a regular follow up examination that should include thorough physical exam and blood tests. A strong emphasis is also put on the need to secure a balanced diet for DS people, being overweight and obesity conditions that often affect these patients that are, at least partially, preventable. From this perspective, implementing physical activity is absolutely crucial, and health and education programmes must be targeted at the families with DS children to inform of the benefits of a correct lifestyle. In this regard, not only the endocrine specialist, but also primary health care plays an important part.

ABSTRACT

Autosomal dominant polycystic kidney disease (ADPKD) is an inherited genetic disorder that results in progressive renal cyst formation and ultimately loss of renal function. Mutation in either *PKD1* or *PKD2*, which are the genes coding for polycystin-1 and polycystin-2, respectively, is the main cause of the disease. The mutation in *PKD1* accounts for 85% of all ADPKD cases, whereas only 15% of ADPKD cases result from *PKD2* mutations. ADPKD is a systemic disorder associated with cardiovascular, portal, pancreatic and gastrointestinal systems. ADPKD is a ciliopathy, a disease associated with abnormal primary cilia. Non-motile primary cilia, functioning as mechanosensory organelles, have been an intense research topic in ADPKD. It has been shown that both structural and functional defects in primary cilia result in cystic kidney and vascular hypertension. In particular, polycystin-1 and polycystin-2 are co-localized to primary cilia and are responsible for mechanosensory induced calcium influx in response to fluid-shear stress. Based on the multiple signaling pathways in ADPKD, different molecular targets have been developed for potential therapies.

1. INTRODUCTION

Polycystic kidney disease (PKD) is a group of renal cyst diseases that are characterized by the formation of fluid-filled cysts. PKD is classified into acquired and hereditary forms. The acquired form of polycystic kidney disease is characterized by long standing chronic renal failure and subsequent dialysis. However, most forms of polycystic kidney disease are hereditary, including nephronophthisis and medullary cystic kidney diseases. The most common hereditary forms of PKD are autosomal dominant PKD (ADPKD) and autosomal recessive PKD (ARPKD). The pathophysiological presentation of these diseases starts from birth in ARPKD and in the adult years in ADPKD. While the key feature of ARPKD is elongated cysts due to collecting duct dilatation, the hallmark of ADPKD is large focal cysts arising from the rapidly dividing tubular epithelial cells. An important difference between the two is that cysts in ADPKD become isolated, while cysts remain in contact with their tubular origin in ARPKD [1].

The estimated prevalence of ADPKD is one in every 500 to 1,000 individuals [2, 3]. ADPKD is caused by mutation in either *PKD1* or *PKD2*, encoding polycystin-1 or polycystin-2, respectively [4-6]. Mutations in *PKD1* are responsible for more than 85% of ADPKD whereas mutations in *PKD2* account for 15%. On the other hand, ARPKD is caused by mutations in *PKHD1* gene, with a prevalence of one in 20,000 live births [7].

In ADPKD, cysts can form not only in the kidney but also in other organs such as the liver, seminal vesicles, pancreas, and arachnoid membrane [8-10]. Clinically, ADPKD is also characterized by vascular abnormalities such as intracranial aneurysms, dilatation of the aortic root, dissection of the aortic thoracic aorta, mitral valve prolapse, and abdominal wall hernias. Imaging studies are primarily used to diagnose ADPKD. Magnetic resonance imaging (MRI) is used to determine kidney volume as well as to exclude intracranial aneurysms, particularly in patients at high risk. Genetic testing is clinically available for both *PKD1* and *PKD2*.

2. PRIMARY CILIA AND CYSTIC KIDNEY

Primary cilia are found on almost all mammalian cell types including renal epithelia where they act as mechanosensory organelles, sensing and responding to urinary flow in the nephron [11, 12]. Previous studies have showed that primary cilia contain polycystin-1 and polycystin-2 [11-13]. Polycystin-1 and polycystin-2 are glycoproteins widely expressed in various tissues, including renal epithelia, vascular endothelia and cardiac myocytes. Polycystin-1, with 11 transmembrane domains, is developmentally regulated [14, 15]. Subcellular localization of polycystin-1 seems to depend on the stage of development and cell polarization of the tubular epithelium [16, 17]. Polycystin-2 is a calcium channel with six transmembrane domains [6, 18]. The transmembrane region of polycystin-2 is homologous to polycystin-1, voltage-activated and transient receptor potential (TRP) channel subunits [19].

Ultrastructurally, the cilium is a hair-like structure filled with microtubules and enclosed by the ciliary membrane. Primary cilia contains the outer nine microtubule doublets, but lack the inner pair of microtubules, and that is why it is known as a “9+0” axoneme. The outer microtubule doublet is connected by a structural protein nexin to form a ring in the primary cilium [20]. The basal body or mother centriole is a region in which doublet microtubules rise

from the triplet microtubules and is known as the transition zone. The basal body and centriole join together and form a centrosome, which serves as the cell's main microtubule organization. The ciliary necklace, which is made of a series of membrane proteins at the transition zone, helps differentiate the ciliary membrane from the cell's plasma membrane [21]. The primary cilium also has ciliary pockets on each side of the plasma membrane [22]. These are invaginations into the cell membrane adjacent to the ciliary necklace common to many species. The semi-enclosed area is created by apertures at the transition zone, known as the ciliary sheath, and is thought to restrict protein and lipid entry into the cilium; this area is formed during ciliogenesis [23, 24].

Within an epithelial cilium, the polycystin complex has been proposed to have a role in sensing and mediating flow dependent mechanosensory calcium signaling [11, 12, 25-28]. The involvement of polycystins in primary cilia has further provided that ciliary dysfunction results in abnormal planar cell polarity [29, 30].

Figure 1. Hypothetical model of cystogenesis. The diagram depicts the mechanosensory function of a renal tubular cilium and how cilia dysfunction can lead to cyst formation. The cilium plays an important role as a mechanosensory organelle that transmits extracellular signals such as urine and blood flow into the cell. These signals may provide critical messages to the cell regarding the direction of cell division along the tubule. A mutation in either *PKD1* and/or *PKD2* will result in ciliary dysfunction in sensing fluid movement. The abnormality in ciliary sensing could result in the loss of many signals, including those regulating planar cell polarity. As a result, the direction of cell division becomes randomized, resulting in increased tubular diameter rather than tubular elongation. Consequently, cyst growth will occur in isolated focal manner along the renal tubules. More cysts illustrated from the neighboring nephrons are depicted on the bottom left corner. The diagram was modified from the original [152].

Within the kidney anatomy, planar cell polarity is defined as an organized arrangement of cells in a plane of tissue perpendicular to the apical-basal axis as a direction for the orientation of cell division. Using cystic kidney mouse models, defects in cilia function have been shown to cause abnormal spindle pole orientation during cell division [31]. It is therefore thought that inactivation of ciliary protein would result in abnormal planar cell polarity, which in turn triggers an increase in renal tubular diameter. It is hypothesized that the net result is the initiation of cyst formation (Figure 1).

3. LIVER CYSTS

The most common extrarenal manifestation of ADPKD is the formation of liver cysts, the severity and frequency of which increase with age. Polycystic liver also occurs as a genetically distinct disease in the absence of renal cysts. The prevalence of liver cysts is between 75 to 90% among ADPKD patients [32]. Their prevalence by magnetic resonance imaging is 58% in patients 15 to 24 years old, 85% in 25- to 34-year-olds, and 94% in 35- to 46-year-old subjects [33]. Hepatic cysts are more prevalent and cyst volumes larger in women than in men [34]. In addition, women who have had multiple pregnancies or have used oral contraceptive drugs or estrogen replacement therapy have worse disease outcomes suggesting an estrogen effect on hepatic cyst growth.

4. PANCREATIC CYSTS

The pancreas, involved in secretion of hormones and gastric enzymes, contains a maze of tubules and ducts involved in carrying the enzymes to the intestinal lumen. Ductal epithelial cells secrete bicarbonate to neutralize the acidic chyme from the stomach [35]. True congenital cysts of the pancreas are rare. Multiple congenital pancreatic cysts are mostly associated with ADPKD, although they are also found in cystic fibrosis, von Hippel-Lindau disease, Ivemark syndrome, and Meckel Gruber syndrome [36]. In the case of ADPKD, a connection between cilia defects and pancreatic pathologies suggested a link with pancreatic lesions. In some cases, remnants of chronic pancreatitis are found in approximately 10% of patients with ADPKD [37, 38]. In addition, other studies in mutant mice with defects in cilia formation have shown several pancreatic abnormalities, including exocrine cell atrophy, ductal dilation, and collagen deposition [39, 40]. Moreover, another mutant mouse study demonstrated that the absence of cilia in pancreatic cells produces pancreatic lesions that resemble those found in patients with chronic pancreatitis or cystic fibrosis [41].

5. DIVERTICULITIS

Patients with ESRD due to ADPKD have a higher prevalence (20%) of colon diverticulitis than do those with ESRD due to other etiologies (3%) [41]. Not only do ADPKD-ESRD patients have a higher incidence of diverticulitis, they also have a higher complication rate associated with colon diverticulitis [42]. Colon perforation, fistula formation, intra-abdominal

abscess, and generalized peritonitis are frequently diagnosed in ADPKD patients [43, 44]. However, colonic diverticula are usually asymptomatic. Major complications of diverticulitis, including perforation-related peritonitis, sepsis and shock, occur in only a small percentage of patients.

6. PAIN

Pain is the most frequent complaint among ADPKD patients. A recent study of 171 ADPKD patients reported that 71.3% of the patients had lower back pain, the most common site of pain in this group [45]. About 30% of this group had radiculopathy symptoms. The second most common site for pain was reported to be the abdomen. Abdominal pain was reported by 61% of ADPKD patients. The character of pain described by these patients varied from a dull ache (49.5%), uncomfortable fullness (42.7%), stabbing pain (40.4%), and cramping pain (33.0%). Chronic headache and chest pain were also reported in these patients. Pain in ADPKD can occur acutely or persist becoming chronic. Cyst rupture or hemorrhage, infected cysts and renal stones are considered the most common phases of acute pain [32]. Progressive kidney enlargement may cause dull, chronic pain by stretching of the renal capsule. Larger renal volumes accompanied by asymmetric, hypertrophic lumbosacral muscle spasm are likely to be the basis of chronic back pain.

7. HYPERTENSION

With the availability of renal replacement therapies for patients reaching ESRD, cardiovascular complications have emerged as the major cause of death in patients with ADPKD [46, 47]. Hypertension is diagnosed in 50–70% of patients usually before any substantial reduction in glomerular filtration rate is observed [48]. Hypertension relates to progressive kidney enlargement and to ESRD, but in some studies has been reported to be an independent risk factor for progression to ESRD [49]. In addition, hypertension occurs at a much earlier age in ADPKD patients than in the general population [50]. About 10–20% of children with ADPKD develop hypertension, and the majority of adults are hypertensive before any loss of kidney function. The median age for diagnosis of hypertension in ADPKD was 32 years for males and 34 years for females, compared to a median age of 45–55 years in patients with essential hypertension [50, 51]. Not surprisingly, the occurrence of hypertension is greater in both male and female ADPKD patients when their affected parents are hypertensive [32]. The pathogenesis of hypertension in ADPKD patients is complex and multifactorial [52].

7.1. Endothelin

Endothelin-1 (ET-1) has been reported to exert multiple effects on renal physiology [53]. In addition, there is good evidence that many renal cell types, including tubular cells, synthesize and are affected by ET-1, indicating its role as an autocrine or a paracrine factor [54, 55]. ET-1 has also been demonstrated to play a significant role in human renal tubular cells, and it can

stimulate collagen I gene expression in human renal interstitial fibroblasts [56, 57]. Moreover, tubular cell proliferation has been reported to be an early feature of precystic tubules in human ADPKD and many rodent PKD models [58].

Several studies have shown that patients with ADPKD have high expression of ET-1 in the renal cystic epithelium [57, 59]. ET-1 is also found to be present in cyst fluid [60]. Another study demonstrated that patients with ADPKD have increased plasma levels of ET-1 compared with healthy controls and patients with essential hypertension [61]. Moreover, endothelium-dependent relaxation is impaired and endothelial nitric oxide synthase activity is decreased in normotensive patients with ADPKD [62]. These alterations cause up-regulation of ET-1 and dysfunction of the NO system, resulting in arterial vasoconstriction [63].

Other studies have demonstrated a physiological role for ET-1 acting via tubular ET_B receptor to regulate sodium and water excretion in kidney collecting ducts [64, 65]. Activation of tubular ET_B receptors inhibits vasopressin action, thereby promoting diuresis and sodium excretion by inhibiting Na⁺/K⁺ ATPase and/or epithelial sodium channels [66]. As a result, ET_B inhibition can potentiate vasopressin action in cysts derived from the collecting duct and consequently stimulate cyst growth [67, 68]. It is also noteworthy that the increased sympathetic activity and circulating ET-1 levels could result from the stimulation of intrarenal renin-angiotensin-aldosterone system due to progressive cyst enlargement, thereby leading to systemic hypertension [69].

7.2. Primary Cilia and Nitric Oxide

Primary cilia regulated nitric oxide (NO) production play an important role in the regulation of vascular tone [70, 71]. In a blood vessel, an abrupt increase in blood pressure or shear stress can be detected by mechanosensory proteins localized in the cilia [72, 73]. Extracellular fluid mechanics can then be transduced and translated into a complex of intracellular signaling, which in turn activates endothelial nitric oxide synthase (eNOS), an endothelial enzyme that synthesizes NO. The released NO diffuses from endothelial cells to neighboring smooth muscle cells, thus promoting vasodilation.

Both polycystin-1 and polycystin-2 are expressed in the endothelial and vascular smooth muscle cells of all major vessels [74, 75]. Mutations in both *PKD1* and *PKD2* have been shown to contribute to hypertension [76, 77], in part by the failure to convert an increase in mechanical blood flow into cellular NO biosynthesis [72, 73]. It has been shown that impaired endothelial dependent relaxation from aorta cells of *PKD1* knockout mice, due to a defect in (NO) release from the endothelium (Figure 2), correlates with a decrease in Ca²⁺ dependent endothelial NO synthesis activity [78]. We also previously reported the loss of response to fluid-shear stress in mouse endothelial cells with knockdown or knockout of *PKD2* [72]. In addition to the mouse data, polycystin-2 null endothelial cells generated from *PKD2* patients that do not show polycystin-2 in the cilia are unable to sense fluid flow. This further indicates that overall major effect of endothelial cilia function is to decrease total peripheral resistance, thereby lowering the blood pressure through the production of NO.

Figure 2. The role of mechanosensory cilia and nitric oxide production in ADPKD. The biochemical production and release of nitric oxide (NO) is dependent on the function of endothelial cilia in the vasculature. In ADPKD, dysfunctional cilia are not able to mechanically sense blood flow, and NO is not produced, resulting in increased blood pressure. The bending of cilia by fluid-shear stress activates the mechanosensory polycystins complex and initiates biochemical synthesis and release of NO. This biochemical cascade involves extracellular calcium influx (Ca^{2+}), followed by the activation of various calcium-dependent proteins including calmodulin (CaM), protein kinase C (PKC) and Akt/PKB). This illustration was modified from the original [153].

A final contributor to loss of vascular tone regulation could be reduction in NO bioavailability secondary to increased reactive oxygen species at least in *PKD2* heterozygous smooth muscle cells [79].

7.3. Angiotensin

Changes in renal structure may play an important role in the pathogenesis of hypertension in ADPKD patients (Figure 3). Cyst enlargement in ADPKD is associated with medial vascular changes and compression of the adjacent parenchyma with resultant areas of renal ischemia and activation of the renin-angiotensin-aldosterone system (RAAS).

Figure 3. RAAS regulation in ADPKD. Renal cysts compress and disrupt the vascular network in the kidney, which leads to ischemic kidney. It was proposed that this would increase the release of renin from the juxtaglomerular apparatus. The increase in renin secretion would eventually accelerate the conversion of angiotensinogen to angiotensin I, which is further converted by angiotensin-converting enzyme (ACE) to angiotensin II. As a result, the angiotensin receptor (AT₁) is activated initiating cascades of responses resulting in hypertension. This illustration was modified from the original [154].

In support of this, hypertensive patients with ADPKD demonstrate significantly greater renal volumes than patients with normal blood pressure [32, 80]. Other components of the RAAS, including angiotensinogen, angiotensin converting enzyme (ACE), angiotensin II receptor and angiotensin II peptide, have also been detected in cysts and dilated tubules in ADPKD kidneys [81]. Activation of the RAAS has been found in normotensive and hypertensive PKD patients, regardless of their blood pressure and renal function [82]. Not surprisingly, the high levels of circulating angiotensin II in PKD patients have been shown to contribute to the development of vascular hypertrophy, which is further implicated in vascular remodeling [83]. In addition, changes in the vasculature during the course of the PKD progression have been observed in both human [84, 85] and animal studies [86, 87].

Increased sympathetic activity has been reported in hypertensive patients with ADPKD, regardless of renal function [88, 89], suggesting that sympathetic hyperactivity could contribute to the pathogenesis of hypertension in ADPKD patients. ACE-I ramipril and the beta-blocker metoprolol are both effective as first-line therapies in hypertensive PKD patients [90]. It is recommended that more aggressive blood pressure control with these agents is necessary in order to be beneficial for ADPKD patients [32]. It should be noted that angiotensin can stimulate the sympathetic nervous system and vice-versa.

8. LEFT VENTRICULAR HYPERTROPHY

Left ventricular hypertrophy (LVH) is well known as a powerful independent risk factor for cardiovascular morbidity and mortality [91]. Increased left ventricular mass index (LVMI)

is associated with worse renal and patient outcomes in ADPKD [92]. Chapman and colleagues further reported in their study that LVH was found in 48% of hypertensive subjects with ADPKD [93]. Their study also showed a significant correlation between hypertension and LVMI, which has been demonstrated in both children and adults with ADPKD. In addition, children whose blood pressure was within the upper quartile of the normal range were found to have a significantly greater LVMI than those with lower blood pressure [94].

Bardaji and colleagues showed that young normotensive ADPKD patients and preserved renal function had increased LVMI and Doppler abnormalities consistent with early diastolic dysfunction in a cross-sectional study of three different groups of ADPKD patients [95]. Another study by Oflaz and colleagues showed that biventricular diastolic dysfunction was present in both hypertensive and normotensive ADPKD patients with well-preserved renal function [96]. Verdecchia et al. reported that hypertensive patients whose nocturnal blood pressure remains elevated demonstrate higher LVMI compared to those whose blood pressure falls at night [97]. Furthermore, Li Kam et al. demonstrated that hypertensive patients with ADPKD who have normal renal function or mild renal impairment have significantly lower nocturnal decreases in blood pressure compared to patients with essential hypertension [98]. Another study has shown that the nocturnal fall in blood pressure was attenuated even in young normotensive ADPKD patients [99]. In this study, a higher LVMI was closely related to the ambulatory systolic blood pressure in normotensive patients. It has also been shown that insulin resistance is significantly associated with LVMI in healthy relatives and patients with *PKD1* mutations independent of other factors known to increase LVMI such as age, body weight, systolic blood pressure and albuminuria [100]. Thus, the stimulation of angiotensin II and the sympathetic nervous system due to hyperinsulinemia may contribute to increased LVMI in *PKD1* patients [100, 101]. However, other factors besides hypertension, including anemia, obesity, and sodium intake, as well as increased activity of the renin-angiotensin-aldosterone system and other genetic factors, may be associated with LVH, in both hypertensive and normotensive ADPKD patients [93]. The etiology of LVH is likely to be multifactorial but hypertension still plays a major role in its development [102].

9. ANEURYSM

ADPKD patients have a higher prevalence (4.0-11.7%) of intracranial aneurysms than the general population (1.0%) [103, 104]. In addition, four to seven percent of patients with ADPKD die from intracranial aneurysm rupture, and such deaths occur at a younger age than in sporadic cases [105]. Intracranial aneurysm rupture seems to be more common in certain families with ADPKD [106, 107]. This indicates that a family history can be an important tool in assessing the risk of aneurysm rupture in ADPKD. Extracranial aneurysm, such as in coronary arteries, abdominal aorta, renal artery and splenic artery, has been reported in ADPKD patients suggesting that these are primary abnormalities [108, 109]. Other potential cardiovascular features reported in patients with ADPKD include biventricular diastolic dysfunction, endothelial dysfunction, increased carotid intima-media thickness, impaired coronary flow and cardiac valvular defects.

10. THERAPEUTIC TREATMENTS FOR CARDIOVASCULAR COMPLICATIONS

Early and effective treatment of hypertension is highly recommended for the prevention of cardiovascular complications in ADPKD patients. Since LVH and hypertension contribute significantly to cardiovascular morbidity and mortality, controlling these factors can positively impact patient health and survival. Antihypertensive treatment with an ACE inhibitor has been shown to reverse LVH over a seven-year follow-up period, thus decreasing an important risk factor for cardiovascular death in ADPKD patients [110]. A seven-year prospective, randomized study in 75 hypertensive patients with ADPKD and LVH compared the effects of rigorous and standard blood pressure control (<120/80 mmHg versus 135–140/85–90 mmHg) on LVH and renal function. Ecker and Schrier suggest that both strategies decreased LVH significantly [46]. In addition, rigorous blood pressure control was considerably more effective in decreasing LVMI than was standard blood pressure control. More patients in the rigorous-control group (71%) achieved normal LVMI than in the standard group (44%). A subgroup analysis showed that patients who received the ACE inhibitor enalapril experienced a significantly greater decrease in LVH than patients who received the calcium-channel blocker amlodipine, despite similar blood pressure control. On this basis, a blood pressure goal of less than 120/80 mmHg has been recommended for patients with ADPKD with hypertension and LVH [46].

11. MODERN THERAPIES TO HALT PROGRESSION OF RENAL CYSTS

Since ADPKD accounts for up to 10% of patients on renal replacement therapy, an effective disease-modifying drug would have significant implications. The identification of *PKD1* and *PKD2* has led to an explosion in knowledge identifying new disease mechanisms and testing new drugs. Currently, there are three major treatment strategies to treat or reduce progression of kidney failure in ADPKD: to reduce cAMP levels, inhibit cell proliferation, and reduce fluid secretion [111, 112].

11.1. cAMP

Cyclic AMP (cAMP) elevation has an inhibitory effect on cell growth in normal kidney epithelial cells, while it stimulates cell proliferation in ADPKD cells [113]. The molecular basis of this may be Protein kinase-A activation of the B-Raf/MEK/ERK signaling pathway [114]. It has also been proposed that hyper-phosphorylation of polycystin-2 by protein kinase-A can contribute to cystic kidney formation by loss of PC2 inhibition of cell cycle progression [115]. Elevated cAMP also results in increased fluid secretion and cyst enlargement by stimulating the apical CFTR channel and specific basolateral transporters [114, 116]. Vasopressin V2 receptor (V2R) is a major regulator of cAMP production and adenylyl cyclase activity in the principal cells lining the collecting ducts [116]. Nagao et al. showed that high water intake can suppress vasopressin and decrease cyst and renal volumes in PCK rats, with a reduced activity

of the cAMP dependent B-Raf/MEK/ERK pathway [117]. The strongest evidence for a pathogenic role of vasopressin in cyst growth comes from a study which demonstrated that deletion of vasopressin in PCK rats by breeding these with Brattleboro rats results in lower renal cAMP levels and near complete inhibition of cystogenesis [118]. The V2R antagonist OPC-31260 substantially reduced cAMP concentrations and inhibited cyst development in several rodent cystic kidney models [119-121]. Tolvaptan, an analogue with higher potency and selectivity for the human V2R, was equally effective in reducing renal cysts in PCK rats [122]. In a recently concluded phase III clinical trial, Tolvaptan slowed the increase in total kidney volume and the decline in GFR over a three-year period in patients with ADPKD [123]. There was however a significant drop-out rate in the treated group and a few patients developed liver enzyme abnormalities which reversed on cessation of treatment. It is worth mentioning that these drugs had no effect on liver cysts, due to the absence of VPV2R in the liver [34].

11.2. mTOR

The mTOR pathway was shown to be directly regulated by primary cilia [124]. In addition, mTOR signaling can be regulated by different signaling inputs and leads to changes in activity of many cellular processes that drive cyst growth [125]. The polycystin-1 protein directly interacts with the Tuberous Sclerosis Complex-2 (TSC2) protein. TSC2 and Tuberous Sclerosis Complex-1 (TSC1) protein are normally found together in a complex. Bonnet et al. demonstrated that combined mutations in *PKD1* and either *Tsc1* or *Tsc2* in compound heterozygous mice was associated with a more severe renal cystic phenotype than in mice with either mutation alone [126]. mTOR activity is regulated by TSC1-TSC2 complex through several cellular inputs [124, 127]. Thereafter, mTOR regulates protein synthesis, lipid biosynthesis, hypoxia response, *de novo* ceramide synthesis, PKC, AKT, fluid secretion, glycosphingolipid metabolism and ion balance, all of which are dysregulated in PKD. Particularly, the activity of mTORC1, mTORC2, PKC, AKT, ERK, IGF-1, CFTR and EGF-1 are all increased in ADPKD patients [124]. It has therefore been proposed that mTOR inhibition can delay cystic growth and expansion in ADPKD kidneys. More specifically, mTOR kinase activity is aberrantly increased in ADPKD patients [128]. Treatments with mTOR inhibitor, such as rapamycin, sirolimus or everolimus, decrease renal cyst size and improve kidney function in cystic kidney models [129, 130] although not in humans [131, 132].

11.3. EGFR

Members of the epidermal growth factor (EGF)-family bind to ErbB (EGFR)-family receptors, which play an important role in the regulation of various fundamental cell processes including cell proliferation and differentiation [133]. Although ErbB2 and ErbB4 have been detected in developing ureteric buds, EGFR is the predominant ErbB receptor expressed in normal adult mammalian kidney tubules [134, 135]. In addition, EGF-ErbB receptor-mediated interaction is a key element in renal tubular cell proliferation, not only in normal kidneys but also in cyst formation and enlargement. EGF is a well-known mitogen for normal renal epithelia and has been shown to stimulate hyperproliferation in renal cystic epithelia [136, 137]. As mentioned above, EGF and EGF-immunoreactive peptide species are secreted into the apical

medium of cultured ADPKD epithelia, and high mitogenic concentrations of EGF have been measured in ADPKD cyst fluids [1]. Interestingly, the increase of EGF-1 can result in ERK activation through Ras and (B-Raf) Raf signaling pathways, which could in turn regulate the TSC1-TSC2 complex in ADPKD patients [125]. Administration of EGFR inhibitors, such as EKI-785 and EKB-569, in some renal cystic models decreases kidney weights and cyst volumes, suggesting a therapeutic potential of EGFR inhibition in ADPKD treatment [138]. In addition, EGF-like growth factors such as TGF- α and heparin-binding EGF have been found to be abnormally expressed in human ADPKD epithelial cells [133, 139].

11.4. Other Potential Targets

Besides cAMP, mTOR and EGF, there are other potential drugs targeting other signaling pathways such as SR, AP-1, c-Src, Raf, MEK, ERK, A3AR, CFTR and IGF-1 [113, 125], all of which are abnormally regulated in patients with ADPKD (Figure 4). A number of drugs showing promise in preclinical models have been or are being tested in clinical trials (Table 1).

Figure 4. The signaling pathway and drug targets in ADPKD cystic cells. The diagram illustrates the mechanism that polycystin-1 (PC1), polycystin-2 (PC2), signaling proteins, molecules, receptors and drugs exert on signaling pathways leading to cyst formation. The green box indicates drug targets proposed for ADPKD. The blue box indicates the reduced molecules and signaling proteins in ADPKD. The orange box indicates the increased signaling proteins in ADPKD, which are thought to be responsible for an increase in cell proliferation including cAMP, EGFR, Ras/Raf/ERK, Src, CFTR, AC, and mTOR activity. In addition, EGFR activation is also enhanced by amphiregulin (AR) that is abnormally expressed in cystic cells through cAMP, CREB and AP1 signaling. Furthermore, altered EGFR and cAMP signaling stimulate mTOR activity by activation of Akt and Ras/Raf/ERK, which inhibit the TSC1/TSC2 complex. The sphingolipid, Na⁺/K⁺ ATPase, Wnt and P2x7 purinergic receptors are also involved in the regulation of mTOR activity. Na⁺/K⁺ ATPase also regulates the KCa3.1 receptor. However, the abnormal cAMP accumulation contributes to the activation of the Ras/Raf/ERK signaling pathway directly or by the activation of Src, which is able to interact with EGFR in its EGFR/ErbB2 heterodimer form. Other receptors that are involved in ADPKD include adenosine receptor-3A (A3AR), vasopressin receptor-2 (V2R) and somatostatin receptor (SR), which regulate activity of adenylate cyclase (AC). This illustration was adapted from the original [112].

Table 1. Current clinical trials in ADPKD

	Drugs	Signaling pathway	Study design	Treatment duration (months)	Clinical phase trial	Clinical trial status	Clinical trials Gov. identifier	Ref.
1	Octreotide	Analogue of somatostatin known to inhibit cAMP pathway in ADKPD and ADPLD	Randomized, double-blind, Placebo controlled and crossover	12	phase 2/3	Completed /failed	NCT00426153	[140, 141]31
2	Lanreotide	Analogue of somatostatin known to inhibit cAMP pathway in ADKPD and ADPLD	Randomized, double-blind and placebo controlled	6	phase 2/3	Completed	NCT00565097	[142]
3	Sirolimus	mTOR inhibitor	Randomized and penlabel	18	phase 2/3	Completed/ failed	NCT00346918	[132]
4	Sirolimus (SIRENA study)	mTOR inhibitor	Randomized, open-label and crossover	6	phase 2	Completed	NCT00491517	[143]
5	Everolimus	mTOR inhibitor	Multicenter, randomized, double-blind, placebo-controlled	24	phase 3	Completed/ failed	NCT00414440	[131]
6	Tolvaptan	V2-receptor antagonist	parallel-arm, double blind and placebo controlled	36	phase 3	Completed	NCT00428948	[123]

Table 1. (Continued)

	Drugs	Signaling pathway	Study design	Treatment duration (months)	Clinical phase trial	Clinical trial status	Clinical trials Gov. identifier	Ref.
7	Lisinopril and Telmisartan (HALT PKD)1	ACE inhibitor [lisinopril] and angiotensin II receptor blocker (ARB) [telmisartan]	Randomized, double-blind and placebo controlled	72	phase 3	Ongoing	NCT00283686	[144, 145]
8	Pravastatin1	A (HMG coA) reductase inhibitors	Randomized, doubleblind, placebo-controlled	36	phase 3	Ongoing	NCT00456365	[146, 147]
9	Somatostatin	cAMP inhibitor pathway in ADKPD and ADPLD	Randomized, single-blind and placebo controlled	36	phase 3	Ongoing	NCT00309283	not available
10	Bosutinib	c-Src inhibitor	Randomized, double-blind and placebo controlled	24	phase 2	Ongoing	NCT01233869	[148]
12	Triptolide	Restore intracellular Ca ²⁺ signaling and inhibit cell proliferation	Randomized and open-label	36	phase 2	Ongoing	NCT00801268	[149-151]

SUMMARY

Since the discovery of *PKD1* and *PKD2*, there has been tremendous progress in studying disease pathophysiology. As a result, many promising drugs have been and are being developed to slow halt or reverse the progression of cystic disease. Given the complexity of disease and the important extrarenal features, it is likely that a range of specific drugs will be needed to treat patients with ADPKD.

ABSTRACT

Hereditary Haemorrhagic Telangiectasia (HHT) or Rendu Osler Weber syndrome (OMIM 187300/ORPHA774) is a vascular hereditary autosomic dominant multiorganic dysplasia. Prevalence is in between 1 to 5,000/8,000 inhabitants around 65,000 in Europe, and 200,000 in USA); although due to founder effect, and insulation, it is higher in some regions as the Jura in France, Funen Island in Denmark and Caribbean Dutch Antilles where the prevalence may be 1 in 1,200 inhabitants. Diagnosis is based on the clinical criteria of Curaçao (Shovlin et al., 2000): epistaxis, telangiectases, first degree relative with HHT, and visceral arteriovenous malformations (AVMs), mainly in lung, liver and brain. For a positive diagnosis, 3 out of the 4 previous criteria are required. A positive genetic test implies also a positive diagnosis.

The clinical diagnosis requires then a detailed medical screening, with involvement of different medical specialties. Penetrance of the disease is variable increasing with age.

Pulmonary arteriovenous malformations (PAVMs) occur in approximately 50% of patients, hepatic involvement in up to 70%, brain AVMs in 10% and spinal in 1%. However the most frequent clinical manifestation of HHT is epistaxis (nose bleeding) normally from light to moderate that affects 93% of patients and is present before the age of 21 in 90% of cases (Faughnan et al., 2009).

The genetic origin of the disease is due to mutations of genes involved in the TGB- β pathway, critical for the normal development of blood vessels (Fernández et al. 2006). The first gene identified was *Endoglin* (*ENG*), responsible for the 39-59% of the HHT cases (HHT 1); shortly after, *ALK1*/*ACVRL1* was discovered to be involved in 25-57% of cases (HHT2). In around 2% of the HHT patients, the mutation is located in the *MADH4*/*Smad4*

gene leading to a combined syndrome of Juvenile Polyposis and HHT (JPHT). A third and a fourth locus have been mapped on chromosomes 5 and 7 with no genes identified at the moment. Endoglin plays a key role in vasculogenesis and arterial/venous differentiation in embryos, as well as in angiogenesis and neovascularization processes in the adult; ALK1 is responsible for the events occurring during the activation phase of angiogenesis. Haploinsufficiency is accepted as the mechanism of pathogenicity for the HHT.

INTRODUCTION

Hereditary Haemorrhagic Telangiectasia (HHT) or Rendu Osler Weber syndrome (OMIM 187300/CIE9 448.0/ORPHA774) is a genetic disease with dominant inheritance pattern leading to a vascular dysplasia characterized by the presence of lesions ranging from small vessel enlargements (telangiectases) to complex arteriovenous malformations (AVMs) or shunts that can potentially affect any organ but mainly lungs, brain, liver and gastrointestinal tract. First described [1] by Henry Gawen Sutton in 1864, it was Henry Rendu in 1886 who recognized it as a different entity from the haemophilia [2]. William Bart Osler in 1901 and Frederick Parks Weber in 1907 published the first series of cases [3,4] but it was in 1909, when Hanes introduced the actual terminology of HHT [5]. Microscopical anatomical findings rely on the presence in a capillary vessel of a direct communication between artery and vein with absence of the intermedium capillary net [6,7]. In the initial phase of the development of the telangiectasia, a dilatation of the postcapillary venules in the horizontal upper plexus in the papillary dermis occurs with the presence of a perivascular infiltration of lymphocytes, monocytes and macrophages; in the intermediate phase, when the lesion reaches a diameter of 0.5 mm, the walls of the postcapillary venule enlarge due to the increase in the number of pericytes while the arteriole can be dilated but still connected by a short capillary system with the venule; at the end when the telangiectasia is completely formed (2 mm), the venules are markedly dilated, elongated and twisted occupying the whole dermis.

Figure 1. Evolution of a Cutaneous Telangiectasia in Hereditary Hemorrhagic Telangiectasia. **A.** In normal skin, arterioles (A) are connected to venules (V) through multiple capillaries (C). The ultrastructure of a normal postcapillary venule includes the lumen (L), endothelial cells, and two to three layers of surrounding pericytes. **B.** In the earliest stage of cutaneous telangiectasia, a single venule becomes dilated, but it is still connected to an arteriole through one or more capillaries. A perivascular lymphocytic infiltrate is apparent (asterisk). **C.** In a fully developed cutaneous telangiectasia, the venule has become markedly dilated throughout the dermis. The connecting arterioles have also become dilated and communicate directly with the venules without capillaries. The thickened wall of the dilated venules contains more than 10 layers of smooth-muscle cells. (Adapted from Guttmacher et al;1995).

These venules have between 8 and 11 layers of plain muscle and disperse quantities of collagen with no elastic fibers; direct connection between arterioles and venules is observed at this stage with disappearance of the capillary net. The perivascular infiltrate of monocytes can still be present in the abnormal vessels at this time (Figure 1).

HHT IS A RARE DISEASE IN SPITE OF ITS AUTOSOMAL DOMINANCE

According to the literature it can be considered a rare disease as its prevalence ranges from 1:5000-8000 worldwide [8]. It is calculated a population of 62500 affected individuals in Europe, and near one million people all over the world. However and due to a founder effect, there are certain areas with a higher prevalence. The most detailed study about prevalence of the disease was presented in 1989 by Plauchu et al., as a result of a research on French population concluding with a medium prevalence in France of 1/8,000 with higher rates in the Jurá area (1/2,351) [9]. The Dutch Antilles is the place with highest prevalence in the world (1/1,1331 in Curaçao and 1/1,331 in Bonaire) [10]. Other areas with high concentration of cases are Akita in northern Japan (1/5,000-8,000) [11], the Fynn county in Denmark (1/1,641-7,246) [12], and more recently in Canary Islands (near 1/3,000) reported in the 10th HHT meeting in Cork (2013) (Table 1).

Table 1. Estimations of prevalence of HHT

Geographic Area	Prevalence	Reference

Table 2. Curaçao clinical criteria

1. Epistaxis	(Spontaneous and recurrent)
2. Telangiectases	(Multiple and in specific locations)
3. Dominant Inheritance Pattern	(a first-degree relative with HHT according to these criteria)
4. Internal Organ Involvement	(pulmonary, hepatic, cerebral, or spinal arteriovenous malformations, gastrointestinal telangiectasias)

HHT CLINICAL DIAGNOSTIC CRITERIA

Nose bleeding [13] is the main and earliest clinical symptom (90% of patients before the age of 21) present in more than 96% of patients. The epistaxis is also the circumstance affecting primarily the quality of life of HHT patients. However, there are certain cases where the pulmonary or the brain AVMs appear before the nose bleeding manifestation, in early ages, mainly children. Diagnosis is based on the clinical Curaçao criteria [14] (Table 2): epistaxis, mucocutaneous telangiectases in typical areas, family dominant pattern and internal organs involvement. Definite illness is diagnosed if three criteria are fulfilled and probable HHT if patient shows two of them. The identification of the causative mutation through molecular study is complementary to the probable or doubtful cases, and definite in relatives of affected families where the mutation for the index case is known. Penetrance is variable but in general it increases with age (90% at the age of 45) [15]. Due to the HHT rare condition, it is highly underdiagnosed all over the world, with a medium delay in diagnosis of patients estimated in about 30 years [16].

CLINICAL SYMPTOMS

Although the most prevalent symptom is the epistaxis due to the rupture of local telangiectases in the nose, almost any organ of the body can be affected, occasionally with important associated morbi-mortality. In a study carried out on a Danish population of HHT patients [12] the mortality observed on HHT patients under 60 years old was higher than the expected for control population within the same age range. Pattern presentations are highly variable among families, even considering individuals of the same family. However, regarding genotype-phenotype correlation, pulmonary and brain AVMs have been observed with higher incidence on HHT type 1 patients, while HHT2 patients are in higher risk of gastrointestinal and hepatic involvement [17].

EPISTAXIS

The inspired air stream shear stress on the nasal mucose causes the rupture of these malformations with bleeding, present in more than 96% of patients. They normally constitute the earliest and more frequent manifestation of the disease. About 50% of HHT patients will present epistaxis before the age of 20. The Kiesselbach area is normally the most affected and usually the intensity increases with age. However sex, climate, diet, stress and pharmacological treatments can influence the frequency and quantity of nose bleeds [18].

There are several scales trying to quantify epistaxis severity: the Sadick scale [19] that considers frequency and quantity, and more recently the HHT epistaxis severity score (HHT-ESS) [20] that estimates frequency, quantity, characteristics of the bleeding, need for medical attention and the presence of anemia.

MUCOCUTANEOUS TELANGIECTASES

They are present in more than 75% of HHT patients and appear normally from the second decade of life. They are usually round, 1-3 mms reddish spots that disappear with vitropression and normally located on lips, tongue, palate, fingers, face and ears (Figure 2).

Figure 2. Typical telangiectases in HHT.

Apart from the presence of a mutation in heterozygous condition, it has been postulated the need for a “second hit” as physical trauma, wounds, or exposition to physical agents to trigger the telangiectases appearance. Due to the extinction of the capillary net and the arteriolization of the circulation, jet-bleedings are frequent when telangiectases break. Sometimes variations on the microscopic capillaries have been observed with a capillaroscopy [21] preceding the onset of macroscopic lesions, this circumstance which can be useful to clinically diagnose HHT in pediatric ages.

PULMONARY AVMS

It is estimated that 25-30% of HHT patients hold pulmonary arteriovenous malformations (PAVMs) while 90% of general patients with PAVMs suffer in fact from HHT. These arteriovenous malformations in the HHT lung patients are morphological and histologically indistinguishable from those present in non HHT ones; however PAVMs in HHT patients are more frequently multiple (35-65% of cases) and bilateral (25%) [22]. Pulmonary AVMs can be of two types: simple (80% of total, they have a unique afferent artery draining to a unique efferent vein through a bulbous, aneurismatic sac) and complex (20% of total, they have two or more subsegmentary afferent arteries connecting through an aneurismatic sac with two or more efferent arteries) [23]. Lesions are more frequent in lower pulmonary lobes due to dynamic blood flow and it is calculated that 25% of PAVMs grow gradually between 0.3 and 2 mm per year. This risk of enlargement is higher in adolescence, pregnancy and situations of high hypervolemia [24]. They can cause hypoxemia, rupture with secondary haemothorax or hemoptysis, paradoxical stroke (10-15% risk if not treated) due to right-left extracardiac shunting and central nervous system infections in case of paradoxical septic emboli [25]. Screening for PAVMs is mandatory in suspected or diagnosed HHT patients to prevent neurological complications that normally increase with age and number of lesions [25]. The most sensitive test to disclose PAVMs is cardiac echocardiography with agitated saline solution that can be graded to evaluate the possibility of finding large AVMs susceptible to be treated [26].

HEPATIC AVMS

Although up to 75% of HHT patients will present liver involvement in image tests [27], it is normally asymptomatic (only 8% have severe symptoms associated with hepatic liver malformations (HAVMs), and characterized by the presence of telangiectases or confluent vascular structures, perfusion disturbances, enlargement of hepatic artery and venous-venous or portal-venous shunting. In cases of severe liver involvement and due to the double irrigation of the organ, we could find three types of shunts: arterio-hepatic (between hepatic artery and suprahepatic veins: these can lead to heart high-output failure), arterio-portal (between hepatic artery and porta vein: these can lead to cirrhosis) and porto-venous (between porta vein and suprahepatic veins) [28]. Heart failure is the most frequent manifestation of HAVMs (63%), portal hypertension occurs in 17% of severe cases and biliary ischemia in 19% of patients (normally associated with higher shunt grades). Other symptoms are portal-systemic encephalopathy (4%) and mesenteric ischemia. Liver biopsy is contraindicated in these patients (it must be considered also the highest prevalence of nodular focal hyperplasia due to HAVMs which can be confused with cirrotic nodules) and endoscopic cholangiography should be also avoided [29].

BRAIN AVMS

Between 10-20% of HHT patients present brain AVMs, representing a much higher incidence than the non HHT population. Lesions can range from telangiectases (40-50%), arteriovenous malformations (20%), to arteriovenous fistulae (20%), which represent direct connections between artery and vein with high flow, dural arteriovenous fistulae (5%) and cavernomatous malformations (5%) [30]. In HHT patients most lesions tend to be multiple (50% of individuals show two or more malformations) [31], with cortical location in almost all cases. Up to 23% of HHT patients present neurological symptoms as migraine, epilepsy, stroke, abscesses or hemorrhage [32]. Risk of bleeding remains controversial, with series that show less possibility compared with the general population (0.5% per year) [33], and others demonstrating over 20 times higher risks, depending on the type of vascular malformation [34] (normally lesions with deep venous drainage, unique drainage vein or high pressures on afferent arteries). Several cases of bleeding in newborn and young children have been described generally secondary to rupture of high flow pial fistulae. Screening with angio nuclear magnetic resonance is advisable at the moment of diagnosis of HHT and in newborns of parents with HHT and positive genetic test.

SPINAL AVMS

Spinal cord lesions in HHT patients are perimedullary intradural vascular malformations with direct connection between artery and vein and high flow [35]. They can be classified into micro and macro fistulae (the latter more frequent in HHT patients) [36]. The presence of a spinal macrofistula in paediatric ages could indicate suspected HHT. Symptomatology can be secondary to bleeding, compression, vascular robbery or venous thrombosis. Screening for

spinal AVMs in young women could be indicated before pregnancy, or prior to delivery to prevent the puncture of lesions in case of epidural anesthesia.

GASTROINTESTINAL BLEEDING

Gastrointestinal symptoms are related with the development of telangiectases in the digestive tract. These normally tend to appear from the fifth-sixth decade of life and the presence of ferropenic anemia due to chronic bleeding is the rule. Although up to 80% of HHT patients can have lesions, only 13-33% present gastrointestinal bleeding [37] and symptoms can very often mistaken with swallowed blood from epistaxis. Digestive tract involvement is higher in the upper areas (stomach and first parts of the small bowel with normally multiple telangiectases) while the quantity of lesions present in jejunum and ileum correlate with the number of telangiectases present in duodenum [38]. Gastrointestinal tract involvement should be suspected when anemia is present in the context of mild epistaxis and existence of telangiectases shown by endoscopic studies (gastroscopy, colonoscopy or videocapsule). Management is difficult mainly in distant telangiectases. Electrocoagulation of lesions should be only tried in a limited number of cases. Pharmacological management is similar to that used for nose bleeding. Surgery should be delayed as the last therapeutic solution for refractory bleeding. HHT patients with mutations in Smad 4 should be considered for early and periodical endoscopic screening to prevent development of local malignancy [39].

HHT Genetics

Considering molecular basis, two loci are involved by mutation in more than 90% of HHT cases. The first gene identified was *endoglin*, that maps to chromosome 9 [40-42] and is responsible of 39-59% of the total HHT cases. Afterwards *ACVRL1* (activin like kinase type 1 or ALK1) was described [43,44], and maps to chromosome 12, being involved in 25%-57% of the HHT reports. Mutations in *ENG* and *ACVRL1* give rise to HHT1 and HHT2 types, respectively. In 2% of HHT patients the mutation is located in the *MADH4* gene (Smad4) leading to a combined syndrome of Juvenile familial polyposis (JPHT) and HHT [45]. A third and fourth locus with a role in the genesis of HHT have been localized on chromosomes 5 and 7 with no identified genes, at the moment [46,47]. The pathogenical mechanism proposed for the HHT is the haploinsufficiency of endoglin, ALK1 or Smad 4 [48,49]. The mutated counterpart gives rise to either RNA which suffers decay for a premature stop codon, codes for a protein which does not reach the membrane surface, or, even reaching the membrane, the product is functionally inactive in the TGF- β signaling cascade. In summary, the endothelial cell harbors only at the most, half of the functional protein (ENG, ALK1 or Smad4) and this amount is not enough to meet the physiological needs of the cell.

A geographical variation has been observed with higher prevalence of mutations in *ALK1* in the Mediterranean regions [50,51] and on *Endoglin* in North America and Northern countries of Europe [52].

The mutations in *Endoglin* and *ALK1* are numerous, of different types including insertions, deletions, duplications, nucleotide changes, splice defects, loss of exons, and loss of the whole

gene. The mutation database of Arup laboratories is in constant modification and with increasing number of mutations <http://arup.utah.edu/database>.

The three identified genes mutated in HHT (ACVRL1, ENG and MADH4) encode for proteins involved in the TGF- β signalling pathway [8].

Figure 3. (A). Schematic distribution of exons in *Endoglin* and *ACVRL1* genes (EC: extracellular domain, CYT: cytoplasmic domain, TM: transmembrane domain). (B). Schematic distribution of different regions in Endoglin and ALK1 proteins.

STRUCTURE OF ENDOGLIN AND ALK1

Both endoglin and ALK1 are type I trans-membrane proteins. The *Endoglin* gene is 40 kb long and was localized on chromosome 9q33-34 by linkage studies and *in situ* hybridization [40,41]. It is composed of 14 exons (exons 1 to 12 encode the extracellular domain, exon 13 encodes the transmembrane domain, and exon 14 encodes the cytoplasmic domain). On the other hand *ACVRL1* gene spans 13 Kb and mapped on 12q11-q14 and it is composed of 9 exons (exons 1 to 3 encode the extracellular domain, exon 4 encodes the transmembrane domain, and exon 5 to 10 encodes the cytoplasmic domain [43,44] (Figure 3A, 3B).

Endoglin is expressed as a 180-kDa disulfide-linked homodimer [53]. It contains a large extracellular domain of 561 amino acids, highly glycosylated mainly in asparagines residues. Structurally, endoglin belongs to the Zona Pellucida (ZP) family of proteins that share a ZP domain of 260 amino acid residues at their extracellular region [54,55]. The third region does not show any significant homology to other protein family/domain and thereby has been named

“orphan” domain. A transmembrane region, spanning 25 hydrophobic residues, acts as a linker between the ectodomain and the cytosolic region.

ALK1 is a transmembrane protein of approximately 55 kDa with an N-glycosylated ectodomain of 97 amino acids carrying a cysteine-rich small sequence which likely confers the appropriate structural conformation to capture the ligand. The ALK1 cytoplasmic region of 362 amino acids contains (i) a GS domain, a conserved 30 amino acids glycine/serine-rich sequence involved in the regulation of the receptor activation and (ii) a serine/threonine kinase domain. Phosphorylation of serine/threonine residues of ALK1 in the GS domain by the type II receptor (T β RII) leads to a conformational change in ALK1 that allows phosphorylation of the downstream signaling molecules Smad1, Smad5 or Smad8 [56].

Figure 4. The TGF- β signalling pathway.

THE TGF- β PATHWAY

Transforming growth factor- β 1 (TGF β -1) is the prototypic member of a large family of evolutionarily conserved pleiotropic secreted cytokines, which also includes the activins and bone morphogenetic proteins (BMPs). Individual family members have crucial roles in multiple processes throughout development and in the maintenance of tissue homeostasis in adult life [57]. Not surprisingly, therefore, subversion of signalling by TGF β family members has been implicated in many human diseases, including cancer, fibrosis, autoimmune and vascular diseases [58-60].

TGF- β signals through a heteromeric complex of type I (RI) and type II (RII) which are transmembrane serine/threonine kinase receptors (Figure 4). Although the core of the TGF- β

receptor complex is formed by the association of RI and RII, it may also contain auxiliary receptors such as endoglin and betaglycan.

First, TGF- β binds RII with a high affinity. This TGF- β /RII complex then recruits RI. Once the heteromeric complex TGF- β /RII/RI is formed, a domain of RI is phosphorylated by RII [57,61]. This phosphorylation of serine/threonine residues leads to RI activation, in turn propagating the signal through a cascade of intracellular effectors which belong to the Smad protein family. There are three different types of Smads: receptor regulated (R-Smads), common mediator (Co-Smads) and inhibitory (I-Smads) Smads. R-Smads like Smad1, Smad2, Smad3, Smad5 and Smad8 are phosphorylated and activated by RI and these activated R-Smads bind subsequently to the Co-Smad, Smad4. The R-Smad/Co-Smad complexes translocate to the nucleus where they contribute to the transcriptional activation of target genes [62]. The I-Smads (Smad6 and Smad7) prevent R-Smad phosphorylation by competing with R-Smads for receptor interaction through recruitment of ubiquitin ligases to the activated receptor leading to its proteosomal degradation, or by recruiting phosphatases that inactivate RI [63,64] (Figure 4).

Several members of the TGF- β superfamily, including TGF- β 1, TGF- β 3, activin-A, BMP-2, BMP-7 and BMP-9 are able to bind endoglin and/or ALK1. This binding triggers the Smad-dependent downstream signalling [65,66].

In ECs, endoglin modulates ligand binding and signaling by association with ALK1 and ALK5 [65-68]. Thus, endoglin inhibits the TGF- β /ALK5/Smad3-mediated cellular responses such as the increased expression of the plasminogen activator inhibitor 1 (PAI-1). By contrast, endoglin promotes the ALK5/Smad2-mediated upregulation of endothelial nitric oxide synthase (eNOS) as well as the TGF- β 1/ALK1-mediated increase of Id1. Interestingly, endoglin inhibits the BMP-9/ALK1 signaling in ECs. Overall, endoglin appears to be a critical modulator of the balance between ALK1 and ALK5 signalling [69-71].

Different studies support the view that endoglin and ALK1 participate in a common signaling pathway that is critical for EC responses to TGF- β family members [70-72]. This conclusion agrees with the fact that pathogenic mutations in *ENG* or *ACVRL1* genes result in HHT and that ALK1 and endoglin null mice have similar vascular phenotypes [73].

FUNCTIONAL IMPLICATIONS OF ENDOGLIN AND ALK1

Endoglin and ALK1 are expressed in endothelial cells (ECs), which are the primary cell target in HHT. Endoglin is expressed at low levels in resting ECs, but at high levels in endothelial proliferating cells at sites of active angiogenesis and during embryogenesis [72]. Other cell types that express endoglin at their surface are macrophages, erythroid precursors in bone marrow, syncytiotrophoblasts and several cell types closely related to the cardiovascular system such as smooth muscle cells of atherosclerotic plaques and cardiac fibroblasts [71].

Upregulated expression of endoglin was found in inflamed or infected tissues, healing wounds, psoriatic skin, synovial arthritis, upon vascular injury and in tumoral vessels [71,74,75]. Under hypoxic conditions, the hypoxia inducible factor-1 (HIF-1) complex binds a functional consensus hypoxia responsive element (HRE) in the *ENG* gene promoter [76]. TGF- β signaling, via Smad transcription factors, also potently stimulates endoglin expression [77,78]. Whereas hypoxia alone moderately stimulates endoglin transcription, addition of TGF- β 1 under hypoxic conditions results in a transcriptional cooperation between both signalling

pathways, leading to a marked stimulation of endoglin expression. This synergic stimulation involves the formation of a transcriptional multicomplex containing Smad3/Smad4, Sp1, and HIF-1 [76]. Upon vascular injury, a transcriptional activation of endoglin mediated by the cooperative interaction between Sp1 and KLF6 transcription factors has been reported [74]. By contrast, tumor necrosis factor-alpha (TNF- α) decreases endoglin protein levels in ECs [71].

Endoglin is also implicated in the cytoskeletal organization. The cytoplasmic tail of L-endoglin interacts with members of the LIM domain-containing family of proteins, including zyxin and ZRP-1 (zyxin-related protein-1), involved in regulating cytoskeleton, assembly and cell motility [79]. The organization of the capillary network during angiogenesis depends on the structure of ECs so that in the vasculature of HHT patients a disorganized cytoskeleton is prone to cell breaking with changes in shear stress and blood pressure. This might lead to vessel haemorrhages and eventual disappearance of the capillary network, as occurs in HHT [80].

On the other hand, expression of endoglin in the tumor cells appears to play an important role in the progression of cancer, influencing cell proliferation, motility, invasiveness and tumorigenicity [72,81,82]. In addition, *in vitro* and *in vivo* experiments in which endoglin expression is modulated, have provided evidence supporting endoglin as a tumor suppressor [83]. Interestingly, increased levels of soluble endoglin have been detected in plasma, serum and urine from patients with different pathologies, including preeclampsia and cancer [72]. This soluble endoglin comes from a proteolytic shedding of the membrane bound protein. MT-1 is the metalloprotease responsible for the cleavage [84]. Circulating soluble endoglin is a reliable marker of preeclampsia and is associated with poor prognosis in cancer. Whereas it has been postulated a pathogenic role for soluble endoglin in preeclampsia due to its anti-angiogenic activity, the role of soluble endoglin in tumor progression remains to be established [83]. Decreased levels of soluble endoglin have been detected in plasma samples of HHT patients, as a reflect of decreased endoglin on the membrane surface [85].

ALK1 expression has been reported not only in highly vascularized tissues including lung, placenta, and heart, but also at specific sites of epithelial-mesenchymal interactions, and in other cell types such as monocytes, microglia, skin fibroblasts, stellate hepatic cells, chondrocytes, neural crest stem cells and more recently myoblasts [67,71]. Nonetheless, most studies to date suggest that its major roles are related to the endothelial specific expression pattern. ALK1 is involved in angiogenesis and a regulatory region of ACVRL1 gene is sufficient for endothelial expression in arteries feeding ischemic tissues [86]. The characterization of ACVRL1 promoter and the study of its transcriptional regulation has begun to be elucidated by Garrido-Martín et al. (2011) and its transcriptional activation upon vascular injury, through Sp1 and KLF6 cooperation has been recently described [87].

GENERAL CLINICAL RECOMMENDATIONS FOR MANAGEMENT OF HHT PATIENTS

Given the risk of multisystemic affection in HHT patients, the international guidelines [88] recommend the performance of a screening protocol to disclose the presence of internal organ involvement. These protocols are in constant revision due to the appearance of new evidences but they constitute a very appropriate initial approach to the correct management of the disease. Although, there is a lack of wide series and clinical trials, due to the rare character

of the disease, and differences regarding health systems; experts recommend to perform in adults a routine blood test, genetic test if available (to identify the causative mutation, cardiac echocardiography with contrast (if positive, a computed tomography scan to identify pulmonary AVMs and subsequent diagnostic/therapeutic angiography), liver doppler ultrasound study, brain angio-magnetic resonance and ENT evaluation. In case of children, this screening protocol tries to disclose brain AVMs (angio- magnetic resonance) and if the child is asymptomatic, pulmonary screening could be delayed till adolescence.

TREATMENT

There is not a definite treatment for HHT and due to its quality of rare disease and the lack of normalized clinical trials, the support therapies either pharmacological, surgical or combination of both are based in the “state of the art” practice.

Epistaxis

The pharmacological handling of the nose bleeding, almost similar as in the case of gastrointestinal bleeding, and in addition to the general measures of local moisturing, tamponage (preferably with neumatic or autodissolving devices) and iron supplies in case of anemia, relies on six possible alternatives:

1. *Antifibrinolytic therapy*: ϵ -aminocaproic and mainly tranexamic acid [89], locally inhibitors of the fibrinolysis on the wall of the telangiectases with stabilization of the clot and, as *in vitro* observed, increase of the quantity of endoglin and transcriptional induction of endoglin and ALK1 mRNA [80]. A clinical trial has been carried out showing decrease in frequency and quantity of nose bleeding with 1.5 g/day of oral tranexamic acid [90].
2. *Antiangiogenic therapy*: the vascular endothelial growth factors (VEGFs) are specific mitogens for vascular endothelial cells and essential in the process of angiogenesis and lymphangiogenesis in most of physiological and pathological conditions. Some series of cases have been reported about improvement of nose bleeding in HHT with bevacizumab, a recombinant humanized monoclonal antibody to VEGF-A ligand, both topical and systemic, but with no long-term effect is observed after its removal [91-93]. Also thalidomide, a suppressor of several cytokines and angiogenic factors (VEGF, TNF- α and interleukine 6) has been shown to improve nose bleeding in short series of HHT patients [94] and also in non HHT patients with angiodysplasias in the gastrointestinal tract [95].
3. *Immunosuppressant drugs*: several cases of HHT patients treated with sirolimus or tacrolimus due to concomitant pathology (transplants) showed improvement on bleeding severity [96]. This effect is likely due to a promoter increase of *ENG* and *ALK1* TGF- β pathway dependent [97].

4. *Anti-oxidant agents*, such as N-acetylcysteine. In a pilot study developed on 43 HHT patients treated daily with 600 mg/day of N-acetylcysteine for an average of 11 weeks, nose bleeding decreased [98,99].
5. *Hormonal treatment*: hormonal therapy with ethynilestradiol alone or combined with progesterone can be useful to alleviate nose and gastrointestinal bleeding in HHT patients [100]. Also danazol seems to have similar results and to be better for male HHT population to avoid estrogenic feminizing side effects [101]. Based on results with tamoxifen on HHT women with breast cancer and on series of patients that showed improvement in bleeding severity [102,103], a study with raloxifene (a selective estrogen receptor modulator indicated for treatment and prevention of postmenopausal osteoporosis and with advantages on cardiovascular profile and prevention of breast cancer), was carried out on postmenopausal HHT women with HHT at a dose of 60 mgrs./day. After a medium period of 18 months 72% of patients improved symptoms considering frequency and quantity of epistaxis. In parallel, molecular bases of raloxifene effects on cells were studied, concluding that raloxifene binds the promotor of endoglin and ALK1, stimulating their transcription [104]. With these data, raloxifene was designed as the first orphan drug for HHT by the European Medicines Agency and the Food and Drug Administration in 2009 (EMA/OD/138/09, EU/3/10/730, FDA/10/3099).
6. Other approaches have been performed with propranolol, a β -blocker that is currently considered the most efficient drug treatment for the infantile haemangiomas. Antiangiogenic properties of propranolol have been tested in endothelial cells to check the availability for topical use in HHT patients showing its capacity to decrease cellular migration and tube formation and also apoptotic effects [105]. Isolate reports with other drugs such as bleomycin have been presented with variable results.

It must be considered the fact that most of the previously cited treatment options (mainly hormonal treatment, antifibrinolytics and antiangiogenics) could lead as a side effect to thromboembolism phenomena. There are reports on HHT patients that show high amounts of VIII coagulation factor and an increased number of deep venous thrombosis and pulmonary thromboembolism [106], so careful estimation of risk-benefit must be considered when taking in consideration the use of any of them. On the other hand in HHT patients with atrial fibrillation or prosthetic heart valves or any circumstance with the necessity or option to be treated with antiplatelets or anticoagulants, risk-benefit should be considered prior being this circumstance a relative but not absolute contraindication for its administration.

In case of failing of the pharmacological approach or impossibility of its administration, a surgical approach (combined with systemic drugs or alone) should be considered. The possibilities in this field can be “minor surgery”: electrocoagulation of the local lesions with argon plasma [107] or laser combined or not with topical estrogens or local injection of bevacizumab [108]; local sclerotherapy with ethoxysclerol that has been proved to be a good option in patients with mild-moderate bleeding [109] or “major surgery”: septodermoplasty [110] with a substitution of the damaged mucosa by a cutaneous implant (it normally improves the clinic but many patients refer dryness and bad smell); nostrils closure [111] has been shown in some series to be a good option and quite well tolerated. Supraselective embolization of maxillary artery branches is reserved only for cases of unstoppable bleeding or preparation for additional techniques as its effects is normally very short in time.

Pulmonary AVMs

In the case of adult patients with HHT and pulmonary arteriovenous malformations, embolization [112] of lesions, even if they are diffuse [113], is recommended (with coils or Amplatzer devices) to reduce the potential risk of paradoxical stroke and septic paradoxical embolism. Malformations with an afferent artery over 3mm were supposed to be in a higher risk of complications but recent articles postulate that risk does not depend on this size and all accessible lesions should be treated [114]. Follow up after treatment is based on computer tomography studies and recommended in the next 6-12 months. In the paediatric population, management is different as the risk of stroke is lower and in most cases if the patient is asymptomatic, treatment is delayed until puberty [115]. All patients with pulmonary AVMs, treated or not, should receive antibiotic prophylaxis in case of procedures with risk of bacteremia, mainly of the buccal area, to prevent development of abscesses [116]. Pulmonary hypertension has been related in some cases with ALK1 mutations but in most cases of HHT it is secondary to liver/heart failure, and it must be managed currently [117].

Liver AVMs

Although more than 70% of HHT patients can present liver involvement, only 8% show symptoms. Pharmacological management of clinical symptomatology associated with high-output heart failure, cirrhosis and cholangitis is the initial measure but in severe cases liver transplantation has been proved the alternative with the highest survival rates [118]. Other alternatives as hepatic artery embolization appear to have higher morbi-mortality rates and worse survival prediction. Some trials with antiangiogenics (bevacizumab) mainly in cases of heart failure have been performed with good outcomes [119]. Follow-up of liver affected HHT patients show the need to undergo a close control mainly for cases with hepatic AVMs as there is favourable response to treatment (either pharmacological/surgical) in 63% of cases and indicating the heart failure and the development of arrhythmias as the most associated symptoms [120].

Brain AVMs

Cerebral arteriovenous malformations when disclosed can be managed as in non HHT patients with embolisation, stereotactic radiation and surgery or combinations of previous [121,122]. There are not long-term results on wide series of these patients and recommendations rely on the need of expertise for the management of these patients and to treat in prevention those lesions with higher risk to bleed (i.e., high-flow pial fistulae). Cerebral abscesses in HHT patients are mostly related with the presence of pulmonary AVMs and normally caused by anaerobic bacteria (mainly *Streptococcus*); they must be treated as in non HHT patients (antibiotics and/or surgery) [123].

Pregnancy

Most of deliveries in HHT pregnant women proceed normally, however, due to dynamic blood flow specific circumstances pregnancy is in a higher risk of enlargement of pulmonary AVMs and bleeding [124], cardiac heart failure [125], epistaxis and mucose telangiectases worsening due to the hormonal natural state while there is no evidence about management of brain AVMs during pregnancy, recommending the guidelines to wait till delivery to perform the specific treatment if needed in this case. Recognition of the HHT condition and the presence of pulmonary AVMs before pregnancy increases rates of survival however pregnant HHT women should be treated as high risk obstetric patients [126].

Pediatrics and HHT

There is no evidence about HHT increased risk for birth defects [127], however a high prevalence of arteriovenous malformations have been disclosed in children at early ages or even at birth [128] bringing on the table the necessity of checkup at this age. Screening for asymptomatic HHT children is under debate but due to the potentially life-threatening manifestations should be considered mainly for brain AVMs [129].

Chapter 85

OSTEOGENESIS IMPERFECTA

Colin R. Paterson*

Medicine in the University of Dundee,
Dundee, Scotland

ABSTRACT

Osteogenesis imperfecta is the most common heritable cause of fractures in children. It is not a single disorder but a large group of diseases most, but not all, being caused by defects of the genes coding for collagen. Autosomal dominant inheritance is the most common finding in familial cases but new mutations occur. Autosomal recessive inheritance does occur and mosaicism is recognized.

The great molecular heterogeneity is reflected in great clinical and radiological variation. Some cases are so severe that survival beyond intra-uterine life is impossible. At the other extreme some patients, undoubtedly affected their family history, have few fractures and live normal lives. Fractures often occur spontaneously and previously asymptomatic fractures in various stages of healing are often found radiologically. While most symptomatic fractures are diaphyseal, all types of fractures including metaphyseal fractures, rib fractures and skull fractures do occur.

Modern management involves good orthopaedic surgery; it is particularly important to avoid prolonged immobilisation of limbs to avoid superimposed osteopenia. Drug therapy, particularly with pamidronate, may be appropriate in children with the more severe forms of the disorder. Specific attention may be needed to scoliosis, basilar invagination or deafness. Good occupational therapy to maximise mobility is important. Children with osteogenesis imperfecta have normal intelligence and good education is vital.

INTRODUCTION

Osteogenesis imperfecta (OI) is the most common bone dysplasia causing fractures in childhood. In western countries it has a prevalence of about 1 in 10,000. It occurs in all races.

CLASSIFICATION AND GENETICS

The most widely used classification of OI based on clinical and radiological features is that of Sillence et al. [1]. These authors suggested four major types, each of which has subsequently been subdivided (Table 1). It is important to recognize that there is little relationship between the Sillence type and the underlying mutation. Each Sillence type includes patients with many different mutations. Nevertheless the Sillence classification has been invaluable over the years in allowing consistent reporting of the clinical features of each case.

Table 1. Clinical features of the different types of OI in the Sillence scheme together with principal subsequent additions

Type	Features	Genetics
I*	Mild disease usually. Blue or grey sclerae. Normal growth	Autosomal dominant New mutations frequent
II**	Severe disease leading to multiple intrauterine fractures, stillbirth or early neonatal death	Autosomal recessive New mutations
III	Severe disease with fractures at birth and progressive deformity. Often very short stature. Dentinogenesis imperfecta common	Most commonly new mutations of autosomal dominant disorder
IV*	Mild to moderate severity. Normal sclerae except in infancy	Autosomal dominant. New mutations frequent
V	Moderate to severe bone fragility. Hypertrophic callus after fractures. Calcification of interosseous membrane	Autosomal dominant
VI	Moderate to severe bone fragility and deformity. Distinctive bone histology	Autosomal dominant
VII	Moderate to severe disease	Autosomal recessive

* Subdivided: IA and IVA have normal teeth; IB and IVB have dentinogenesis imperfecta.

** Subdivided: A, B and C in relation to the radiological findings.

In recent years a group of clinicians in Montreal has suggested the addition of three further types, V, VI and VII (Table 1). Type V patients were earlier included in type IV but were distinct in having a tendency to form hyperplastic callus after a fracture and calcification of the interosseous membrane of the forearm. These patients were also distinctive in having an IFTM5 mutation [2]. Patients with OI type VI were also clinically similar to type IV patients but had distinctive bone histology with an excess of osteoid. They had a distinctive mutation in

SERPINF1 [3]. OI type VII is the name given to an unusual form of severe OI inherited in an autosomal recessive manner found in a small group of indigenous people in northern Quebec [4]. It is not thought to be caused by a mutation in the collagen genes.

Even among patients with the same mutation there is considerable variation in clinical severity [5]. Similarly within a single family the severity of the disorder may vary greatly. The reason for these variations is not known. One exception is provided by parental mosaicism in which, for example, a clinically normal parent or a mildly affected parent has a severely affected child [6-8]. A further cause for variation within a family occurs when parents who are heterozygous for a mutation and show minor features of OI have a child who is homozygous for the mutation and severely affected [9].

BIOCHEMICAL CAUSES

The mechanical strength of bone depends in part on its content of type I collagen and abnormalities of collagen have been thought since the 1970s to underlie OI [10]. Chemical studies of collagen produced by cultured fibroblasts from patients with OI showed abnormalities. In addition families with dominantly inherited OI had consistent linkage to the two genes coding for type I collagen, COL1A1 and COL1A2 [10, 11].

In 1985 the first mutation was identified, an internal deletion in COL1A1 that had caused a lethal form of OI [12, 13]. By 2007 no less than 832 distinct mutations had been reported [14]. Most of these are private mutations, mutations unique to one individual or family. Deletions are now thought to be an uncommon cause of OI. Exon skipping, due to mutations at splice donor or acceptor sites, is more common. The most common type of mutation by far causes the substitution of a single amino acid.

The structure of a collagen molecule is a triple helix of two alpha 1 chains and one alpha 2 chain. Both contain glycine residues at every third position. These are important structurally; their replacement by bulkier residues distorts the triple helix and prevents the neat packing of molecules into fibrils. Most of the recognized mutations in OI involve substitutions of glycine [15, 16].

The correlation between the nature of the mutation and the clinical features in affected patients is very imperfect. For example substitution of glycine by serine in the alpha 1 chain causes a more severe disease than the same substitution in the alpha 2 chain [5]. In addition a single mutation in apparently unrelated families can result in substantial variation in the clinical phenotype in terms of severity and associated findings [5]. One further cause of clinical variability is somatic mosaicism; an unaffected or mildly affected parent may be associated with a severely affected child [6, 7]. In general blue sclerae are more associated with COL1A1 mutations, particularly those near the amino terminal. Dentinogenesis imperfecta (DI) was most common with mutations in the central region and near the carboxy terminal both in COL1A1 and COL1A2.

It should be noted that mutations in the genes coding for type 1 collagen are not the only causes of OI. It has long been recognized that a minority of patients with OI have no evidence of a mutation in COL1A1 or COL1A2. Some patients have a clearly autosomal recessive inheritance. Many of these disorders are now known to be caused by mutations affecting the proteins involved in the formation of mature collagen.

The formation of collagen is a complex process. The precursors of the alpha 1 and alpha 2 chains are known as procollagens and have peptide chains at both amino- and carboxy-terminals in addition to the future helical portions. These procollagen chains undergo several further steps including the hydroxylation of some proline residues to hydroxyproline with the enzyme prolyl hydroxylase. The procollagen chains come together to give the triple helix and the additional chains at each end are cleaved off. Mutations affecting one of the cleavage sites cause an unusual form of OI with dense bones [17, 18].

Mutations leading to OI, often as a recessive disorder, have now been identified in genes coding for each of the proteins involved in a complex consisting of prolyl 3-hydroxylase, cartilage-associated proteins (CRTAP) and cyclophilin B [19, 20]. Further genes in which mutations have been shown to cause recessively inherited OI include FKBP10, which also causes Bruck syndrome with contractures, and SERPINF 1, which causes OI type VI [3, 21]. OI type V is an autosomal dominant disorder caused by mutations in the gene IFITM5 which codes for a skeletal protein, BRIL, whose function is not yet known [2]. The many mutations that have been shown to underlie OI are recorded in a continuously updated database [22]. Collagen maturation is dependent on the availability of both copper and ascorbic acid. Collagen defects leading to symptoms including fractures are well recognized in copper deficiency and in scurvy.

CLINICAL FEATURES

While the hallmark of the disorder is the increased tendency to fractures other clinical signs may be present. These include blue or grey sclerae, increased joint laxity, impaired growth, liability to bruising, odd shaped skull, dentinogenesis imperfecta, excessive sweating and premature deafness. Most but not all of these clinical features can be associated with the disorders of collagen which are thought to underlie most cases. Few patients have all these signs and some, undoubtedly affected on the basis of family history, have none.

Fractures

The fractures may occur with little or no recognised trauma or with normal handling. Some asymptomatic fractures may be found when X-rays are taken for other reasons. Fractures usually occur without evidence of any local bruising because little trauma is involved. The increased liability to bruising or petechial haemorrhages is thought to result from the increased fragility of small blood vessels [23]. The paradox that fractures occur with few bruises in a child who also has an increased liability to bruising is shared with other bone disorders that cause fractures [24].

In OI fractures may be unpredictable; there may be long gaps between symptomatic fractures in an individual patient (Figure 1). It should be noted that the fracture rate diminishes in the teenage years in all types of OI. In older men the fracture rate remains low in later life but in women there is an increase in fracture rate, particularly vertebral crush fractures after the menopause (Figure 2) [25].

The fractures of OI may include symptomatic long bone fractures, including transverse, oblique and spiral fractures [26]. Metaphyseal fractures are well recognized and usually asymptomatic (Figure 3).

Figure 1. Incidence of fractures in 14 patients with OI type IVA for whom complete records were available for at least eight years. In two cases details were not available for later than the point marked with a star. Data of Paterson et al. 1987 [77].

Figure 2. Fractures per patient per year in relation to time of the menopause in 30 women with OI type IA. Data of Paterson et al. 1984 [25].

Skull fractures are well-recognized [27]. Rib fractures occur and are usually asymptomatic. That these do occur is illustrated by Figure 4 which shows a child on the day of birth later thought to have OI type III. Multiple rib fractures of different dates are seen; all occurred *in utero*.

Figure 3. Metaphyseal fractures of both femora in a three day old child later recognized as having OI type IVA.

Figure 4. Chest x-ray of a boy on the day of birth showing multiple rib fractures of different ages, all of which had occurred *in utero*. He was later thought to have OI type III.

One specific cause of symptomatic fractures in OI needs to be highlighted. The standard tests for congenital dislocation of the hip are those of Ortolani and of Barlow. Carrying out such tests in infants with OI, or whose family history implies that they may have OI, is not advisable; fractures of the femur may occur (Figure 5) [28].

Figure 5. Bilateral femoral fractures found after an examination for congenital hip dislocation in an infant girl with a family history of OI type IVB.

Dental Abnormalities

Dentine also contains collagen and a substantial proportion of OI patients have overt dentinogenesis imperfecta (DI). The teeth are discoloured, translucent and fragile. The severity varies greatly among OI patients. Detailed study of the teeth, including scanning electron microscopy, has shown that all OI patients have abnormalities in the teeth [29]. It should be noted that DI can exist without OI; this disorder is known as DI type II [30]. It is also inherited as an autosomal dominant.

Sclerae

The grey or blue sclerae are among the best known features of OI. They are present in about two thirds of patients and play a part in the conventional classification. The scleral discolouration is thought to reflect thinness of scleral collagen so that the underlying pigment shows through. The assessment of scleral colour is not an exact science; attempts to quantify it using a paint colour strip have not been widely used. Also it should be noted that some blue colouration is seen in normal infants.

Premature Deafness

Hearing loss can occur in all types of OI. Most of the patients who develop hearing loss have their first symptom before the age of 40 but a few have a later age of onset (Table 2) [31, 32].

Table 2. Age of onset of hearing impairment in 77 patients out of 133 OI patients aged 17 or more (32)

Age range	Number of patients
0-10	1
10-20	19
20-30	27
30-40	12
40-50	10
50-60	4
60-70	2
70-80	1
80-90	1

Table 3. Proportion of OI patients of each type who had symptoms of hearing impairment at age 30 [31]

Sillence type	Number of patients aged 30 or more	Number of patients with hearing impairment at age 30	Percentage affected at age 30
IA	276	90	33
IB	60	18	30
III	23	12	52
IVA	32	3	9
IVB	52	15	29
Uncertain	18	7	39

Table 3 shows the likelihood of developing deafness in each type of OI. Most surveys have shown that the deafness associated with OI has no single cause. Most patients have a mixed pattern; smaller numbers have sensorineural or conductive patterns [32, 33].

Cardiovascular Problems

Hypertension appears to be common in adults with OI [34]. Valvular heart disorders, particularly aortic and mitral regurgitation, are also found and often require surgery [34, 35].

Excessive Sweating

Excessive sweating has long been recognized as a symptom in children with OI but no explanation can be made from collagen biochemistry. A postoperative febrile response is more common in children with OI than in normal controls but appears to be harmless [36].

Joint Laxity

Increased laxity of joints is seen in a substantial minority of patients with OI. It may lead to confusion with the Ehlers-Danlos syndrome, some forms of which also result from mutations in the genes coding for collagen. Joint laxity may contribute to the disability resulting from OI, for example in permitting hyperextension of the fingers or in causing instability of the ankles.

Neurological Problems

Basilar invagination is an uncommon but very serious complication of OI and some other bone disorders. It consists of the upward displacement of parts of the occipital bone surrounding the foramen magnum leading to pressure from the upper cervical spine on the brainstem. Symptoms include headache in the neck and occiput, often worse with coughing, sneezing or straining, trigeminal neuralgia, giddiness, weakness in the arms or legs and bladder disorders [37]. Among the physical signs are nystagmus, facial spasm, nerve paresis, proprioceptive defects, pyramidal tract signs and papilloedema [37]. The change in the skull shape may lead to changes in the face including recession of the maxilla and prominence of the mandible (prognathism). While basilar invagination occurs in all types of OI, basilar invagination with neurological consequences is most common in OI type IV B [37].

Intracranial haemorrhage may occur in OI [38, 39] and is a significant cause of death [40].

Impaired Growth

Post-natal growth is normal in many cases of OI type I, reduced in most type IV cases and substantially reduced in OI type III. There is no evidence of growth hormone deficiency [41, 42].

Temperament

One striking feature of many OI patients is their generally positive approach to life often despite appreciable disabilities. This has been confirmed formally [43, 44]. Educational achievements are usually normal despite disabilities [43].

Life Expectancy

Life expectancy is normal in OI type IA, marginally reduced in OI types IB, IVA and IVB, and appreciably reduced in OI type III [45]. Most patients with type I and type IV forms of OI have a normal lifespan and die of causes unrelated to their OI. In many type III patients premature deaths are caused, particularly in childhood, by respiratory problems resulting from kyphoscoliosis. OI plays a direct part in deaths due to basilar invagination and intracranial haemorrhage.

RADIOLOGY AND DENSITOMETRY

The wide range of clinical severity in OI is reflected in a wide range of radiological appearances. Patients with OI types II and III usually have obvious abnormalities from and often before the time of birth. These include fractures which have occurred *in utero* (Figure 4). Most patients with type I and type IV OI have radiologically normal bone at birth. Radiological appearances often remain normal throughout life in bones which have not sustained fractures.

One radiological sign may be helpful in diagnosis. Wormian bones are additional bones, usually in the occipital part of the skull, completely surrounded by a suture line. Conventionally more than 10 such bones are regarded as significant for the diagnosis of OI. In a recent study significant numbers of Wormian bones were seen in 35 percent of patients with OI type I, in 78 percent of patients with OI type IV and in 96 percent of patients with OI type III [46]. It is important to note that excessive numbers of Wormian bones may be found in other disorders including cretinism, cleido-cranial dysostosis and Menkes syndrome [47].

Densitometry

Attempts to assess bone density from ordinary X-rays are imprecise and should not be used [48]. It is inappropriate to comment that a “normal” appearance on ordinary X-rays excludes OI or any other bone disease. However it is true that a substantial number of OI patients have low values when formal densitometry is undertaken.

In our experience of adults with OI (for whom we had a well established reference range) most patients were below the mean for the reference group but many had a higher bone density than the lower reference limit (minus 2 standard deviations) [49]. Similar findings were obtained with DXA of the spine [50, 51]. In one study [51] the authors commented that in “some mildly affected patients brittleness may exist with only small reductions in bone mineral content.”

In children there are only small studies and none of the reference ranges used were satisfactory [52-54]. However it is likely that, as in adults, children with OI have lower bone densities compared with controls but with an appreciable overlap. One difficulty in this field is the continuing lack of robust reference ranges appropriate for the densitometers used.

One further difficulty affecting both adults and children is that a fracture with a period of immobilisation may itself lead to diminished bone density of the limb concerned. This may lead to false assumptions about bone density in the underlying condition. This problem is illustrated in Figure 6.

Figure 6. Hand and foot of a young woman with OI type IVB. The hand (left) shows normal appearances while the foot appears severely abnormal. During her childhood and adolescence she had had multiple fractures in the legs.

CLINICAL BIOCHEMISTRY

Routine investigations such as serum calcium, inorganic phosphate and alkaline phosphatase usually show no abnormality in OI. One exception is that serum alkaline phosphatase may rise if there are multiple healing fractures. It is important to note that normal findings in these tests do not exclude OI.

A number of other biochemical abnormalities have been found in some patients with OI. These include a high urine calcium [55], a high urinary excretion of cross-linked collagen peptides [56] and low serum levels of carboxy-terminal propeptides of human type I procollagen (PICP) [57, 58]. None of these investigations has been evaluated as a test for OI.

One recent study suggested that some children with OI may also be deficient in vitamin D [59]. The actual levels were not given but it seems likely that children with any disability are at risk of spending less time exposed to sunshine than their peers.

Table 4. Percentage of positive findings in known cases of osteogenesis imperfecta investigated by collagen analysis and by mutation detection

OI type	Collagen analysis	Mutation detection
Type I	94%	94%
Type III	84%	81%
Type IV	84%	69%
Type unknown	50%	—

Collagen analysis data of Wenstrup et al. [76]. Mutation detection data in personal communication from Dr D Prockop May 2000

Biochemical investigations used for the diagnosis of OI are of two main types. Some examine the chemistry of the collagen from cultured fibroblasts derived from skin biopsies [60]. Others search for mutations in the genes coding for type I collagen. These tests are useful in the confirmation of OI in cases in which it is not clinically obvious. However there is no information on the likelihood of finding abnormalities in a large unselected group of OI patients. As a result we have little information on the frequency of false negatives. Table 4 shows the findings in two studies; they indicate that in both false negatives are most likely in patients in whom the clinical findings are least helpful. It is not correct to say that a negative result excludes OI.

DIFFERENTIAL DIAGNOSES

In the past numerous cases of OI have initially been diagnosed as child abuse [61-64]. Children with OI may have fractures that the parents or carers cannot explain (Figure 7). They may then be found to have other fractures not clinically suspected; they may have multiple fractures of different ages. The bones may otherwise appear to be normal on ordinary X-rays. It is not surprising therefore that cases of misdiagnosis occur. However it is likely that a substantially larger number of cases of misdiagnosis result from other bone disorders which also mimic accepted descriptions of abuse [24]. These include the osteopathy of prematurity and vitamin D deficiency rickets.

Figure 7. Fracture of left femur in a boy of four months, one of twins. Since the bone appeared normal radiologically it was assumed that considerable force was involved and a care order was sought for both boys. However it later became clear that his father, uncle and grandfather all had pale blue sclerae, dentinogenesis imperfecta and a typical history of OI. By the time of the hearing the boy and his twin brother had obvious dentinogenesis imperfecta.

MANAGEMENT

It is likely that occupational therapists, physiotherapists and orthopaedic surgeons have more to contribute to the management of these patients than any drug therapy but it is important to review the current position.

Drug Therapy

Many drugs have been tried in OI including calcium, anabolic steroids, vitamin C, calcitonin and fluoride. None of these has been shown to be of value in properly controlled trials. The practical difficulties in mounting such trials in OI are substantial because of the variable natural history..

Short stature is a common feature of OI and several trials of growth hormone have been undertaken [65]. While growth velocity increased in the treated group the differences were small and there was no evidence that the final height would be improved. There is no evidence that growth hormone deficiency plays any part in the short stature of OI.

Numerous trials have been undertaken in recent years of various bisphosphonates including alendronate, neridronate, olpadronate, risdronate and zoledronic acid. By far the greatest number of studies have involved pamidronate usually by cyclic intravenous infusions [66, 67]. All the studies found that bone turnover decreased and bone mineral density increased. Many studies have reported a decrease in the number of fractures in the more severe types of OI. However, in some of these the comparison was only with pre-treatment fracture rates; it should be remembered that the fracture rate in untreated OI is extremely variable, often decreasing with age.

The underlying premise in many of these studies is that a rise in bone density is in itself a good thing. However it should be recognised that bisphosphonate treatment in anyone will decrease bone turnover and increase bone density. Decreased bone remodelling may have long term disadvantages for fracture risk. At present it seems that cyclic bisphosphonate therapy is probably advantageous for children with the more severe types of OI but not for adults or for children with milder forms of OI.

One report described clinical responses to bone marrow transplantation in children with severe OI [68]. While initial results were encouraging this strategy does not appear to have been pursued since.

In postmenopausal women with OI the case for low-dose hormone replacement therapy probably outweighs the case against.

Pain Relief

In children, as in adults, pain relief is important after fractures. Paracetamol is effective in mild to moderate pain. For more severe pain non-steroidal anti-inflammatory drugs may be helpful as are opioids.

Orthopaedic Surgery

Good orthopaedic care is needed for fractures to avoid deformity, and therefore increased risk of subsequent fractures. However the period of immobilisation should be minimised to reduce the risk of superimposed disuse osteoporosis. Various forms of intramedullary fixation including telescopic rods can be used in children with recurrent fractures [69].

Scoliosis is common in OI. The conventional view is that if the scoliosis does not exceed 45° conservative management is appropriate. Bracing is ineffective. If the scoliosis exceeds 45° it is thought that posterior spinal fusion is justifiable. However surgery is often difficult because of bleeding and the innate fragility of the bone. Newer techniques appear to be effective [70].

Surgery for Basilar Invagination

Basilar invagination with neurological complications is treated surgically by a transoral clivectomy. This not only halts disease progression in most patients but also provides a sustainable long-term functional outcome [71, 72].

Deafness

As with deafness in general the first step involves the use of hearing aids. In OI, particularly with conductive deafness, stapes surgery usually has good long-term results [73, 74]. In appropriate cases cochlear implantation is a safe and feasible procedure [75].

Dental Care

Good dental care is important in OI, particularly in patients with overt dentinogenesis imperfecta. The teeth in this condition are not only discoloured but fragile. Veneers may be useful for cosmetic reasons but do not contribute to strength.

Some cola drinks are particularly undesirable because of their acidity. Supplemental fluoride may be desirable.

Education

Despite the disadvantage of repeated hospital admissions children with OI do well in education; many have above average potential [43]. A good education is of vital importance for the future. In general, mainstream education is usually preferable to schools for the disabled.

ACKNOWLEDGMENTS

I am grateful to Dr. Elspeth Paterson for her careful review of this paper in draft, and to Mr. Jake McLaughlin and Ms. Kirsteen Bovill for excellent secretarial assistance.

Chapter 86

AUTOSOMAL DOMINANT DISORDERS ASSOCIATED TO BREAST CANCER

Nelly Margarita Macías-Gómez*

Laboratorio de Genética Humana; Departamento de Salud y Bienestar. Centro
Universitario del Sur. Ciudad Guzmán, Jalisco, México

ABSTRACT

The sudden rise of new biochemical and molecular techniques, have enabled a better understanding of the physiological and biochemical bases of the tumorigenesis, leaving clear that cancer is a “*genetic condition*”. Breast cancer is one of the most common cancers in women, affecting one in six women among 40-59 years in the world; so it has been widely studied. Unlike the majority of genetic diseases, in which the presence of a mutation in a particular gene is sufficient for delineation of a phenotype (monogenic); in breast cancer, the simple presence of a mutation in a particular gene is not enough to explain it. Approximately 90% of breast cancer cases occur sporadically and the majority of cases are caused by mutations in the *BRCA1* or *BRCA2* gene. However, in 5-10% of cases of breast cancer has been identify an autosomal dominant transmission, as well as mutations in specific genes such as *TP53*, *PTEN*, *CHECK2* *STK11* among others, that considerably increase the susceptibility to this condition. Autosomal dominant transmission of this disease has opened a new chapter in cancer medicine since the presence of any of these mutations in a patient, forces the doctor to carry out a deep investigation of the condition in order to establish a prognosis, as well as effective strategies for survival and family prevention. This chapter makes a brief revision of the autosomal dominant disorders Li-Fraumani syndrome, Cowden Disease and Peutz-Jeghers syndrome, which have a high susceptibility to development of breast cancer.

BREAST CANCER

The sudden boom of biochemical and molecular techniques, have enabled us to a better understanding of the physiological and biochemical bases of the tumorigenesis, leaving clear that cancer is a genetic "condition". Breast cancer is a disease in which the different cells from breast gain the ability to grow, multiply and become immortal. Is the most common cancers in humans, so it has been widely studied; however, until now there are many questions about the mechanisms involved in their development where several factors as hormonal, reproductive, life style and inheritance play an important role. Even breast cancer mortality has declined in the last 10-15 years (2.3% per year) due to the innovation of diagnostic techniques and more effective treatments, still is a health problem in reproductive women because each year is reported an incidence of 1 million cases, representing 200,000 cases in the EU (27% of all cancers in female) and 320,000 cases in Europe (31% of all cancers in female) (Neville, 2001, Dumitrescu, 2005). In women from United States, breast cancer is the first cancer which represents 22-32% of all types of cancer, as well as being the second cause of death followed by lung cancer (Thull, 2004, Garber, 2005). According with Globocan in 2008 was reported 1'384, 155 new cases of breast cancer, which represent the 22.9% of all types of cancer and a mortality of 458,503 (13.7%) (<http://globocan.iarc.fr/>). Is estimated that a woman who lives 85 years, has one to nine chance of developing breast cancer, however, this risk is not homogeneous for the entire population, since while some women never develop breast cancer, the risk is increased for others. Epidemiological studies in different populations, have been the identification of well established factors that increase or decrease the risk for developing cancer of the breast, as well as other factors that is necessary to conduct more studies in order to identify their contribution (table 1) (Dumitrescu, 2005, Singletary, 2003).

Table 1. Risk factors to Breast Cancer

Biological and geographic	Age
	Gender
	Geographic localization
	Race/ Ethnicity
	Hormonal/ Reproductive
Life Style	Alcohol/ Folates
	Diet
	Obesity
	Physical activity
Genetics	Familiar History
	Syndrome associated to Breast Cancer development
Others	Endometriosis
	Tobacco
	Breast density
	Bening breast lesion
	Radiation exposure
	Bone density
	Intake of aspirin and INES

Among the genetics risk factors has been well known, that the affection of a family member with breast cancer is a strong risk factor, and this risk is estimated depending on the type of cancer, degree of relationship (first or second degree), age at which the family developed the cancer and the number of relatives affected in the family. In this regards, has been estimated that a women with a familiar history in first degree with breast cancer at 50 years or over, have a increase relative risk (RR) of 1.8 and who develop before at 50 years it's RR is 3.3. Similarly, when there is a history of two affected relatives in the first degree, the RR increases to 3.6 and, 3.9 when affected relatives are more than two (Dumitrescu, 2005, Glover, 2006, Antoniou, 2006). Although approximately 10-20% of breast cancer cases are attributed to hereditary factors, only 5-10% of patients has been identified a specific mutation in high penetrant genes that are transmitted in autosomal dominant manner, and the most widely identified are *Breast Cancer 1 (BRCA1)* and *Breast Cancer 2 (BRCA2)*. Recently, had been delineated a group of syndromes autosomal dominant that share the susceptibility to develop several types of cancer, including breast cancer: the Li-fraumeni syndrome which has mutations in the *TP53* gene (*Tumor protein 53*), Cowden syndrome with mutations in *PTEN* gene (*Phosphatase and tension homolog*) and Petz-Jeghers with mutation in *STK11* gene (*Serine / threonine kinase 11*) (Dumitrescu, 2005).

LI-FRAUMENI SYNDROME

Li-Fraumeni syndrome (*LFS*) (MIM-#151623), described for the first time in 1969, is a heterogeneous condition autosomal dominant, with high penetrance. *LFS* is characterized by the appearance of different types of cancer during the childhood of an individual, as well as several members of the family. The life time risk for cancer develops in patient with *LFS* is of 73% in males and nearly 100% in females, with the high risk of breast cancer accounting for the difference. Additionally, is important to consider the age of patient, due to the specific risk for males is 19% before to 15 years, 27% between 16-45 years and 54% in older than 45 years. The risk for females is 12 before 15 years, 82% between 16-45 years and 100% in older than 45 years (Malkin, 2011; Evans, 1997). Has been described that *LFS* family member diagnosed with cancer has a 15% to develop a second cancer, 4% develop a third cancer and 2% has a fourth cancer (Hisada, 1998; Mai, 2012). One of the main types of cancer who develop *LFS* patients is breast, which is of early presentation (< 40 years) and usually bilateral. *LFS* is responsible for approximately 1% of familial breast cancer syndrome. The median age of diagnosis of first malignancy is 25 and approximately 50% of *LFS*-associated malignancies occur by age 30 years. The median age of onset of breast cancer diagnosis in carriers is about 33 years and no occurred after age 50 years. Overall, woman with *LFS* has a breast cancer risk of 56% by age 45 and greater than 90% by age 60, with a majority of the cancers occurring under age 40. If the *LFS* is done, the NCCN guideline suggest the patient being monthly breast self-examinations at age 18, biannual clinical breast exams to begin at age 20-25, and annual imaging with mammography and /or MRI at the same ages, or 5-10 years prior to the earliest known breast cancer in the family kindred (Gage, 2012). Other cancer types presentation in patients cancer are, sarcoma of soft tissues, gastrointestinal (colon, gastric, pancreatic) cancer, lung cancer, osteosarcoma, hematopoietic cancer such as leukemia and lymphoma, adrenocortical carcinoma, brain tumors. Often is diagnosed in early infancy according to the

diagnostic criteria (table 2), and approximately 50% of cases are diagnosed at the age of 30. Families or individuals that do not have all the criteria necessary to the LFS diagnosis have been termed LFS-Like (LFS-L) (Mai, 2021; Neville, 2001, Thull, 2004, Garber, 2005). For more information about diagnose criteria review: www.nccn.org and www.iarc.fr.

Table 2. Li-Fraumani syndrome and Li-Fraumani-like syndrome criteria for genetic testing (Mai, 2012)

Classic Li-Fraumani syndrome (LFS)	Patient who developed sarcoma before age 45 and Have a family member in first grade with any type of cancer (< 45 years) and A first or second degree relative with any cancer before 45 years or sarcoma at any age
Li-Fraumani- like syndrome	Birch definition: • A proband with any chils cancer or sarcoma, brain tumor or adrenocortical carcinoma diagnosed before age 45 years and • A first or second degree relative with a typical LFS cancer at any age and • A first or second degree relative with any cancer before age 60 years Eeles definition: • Two first or second degree relatives with LFS-related malignancies at any age
Chompret criteria	A proband who has • A tumor belonging to the LFS tumor spectrum (soft tissue sarcoma, osteosarcoma, pre-menopausal breast cancer, brain tumor, adrenocortical carcinoma, leukemia, or bronchoalveolar lung cancer) before age 46 years and • At least one first or second degree relative with an LFS tumor (expect breast cancer if the proband has breast cancer) before age 56 years or with multiple tumors Or • A proband with multiple tumors (except multiple breast tumors), two of which belong to the LFS tumor spectrum and the first of which occurred before age 46 years Or • A proband who is diagnosed with adrenocortical carcinoma or chorois plexus tumor, irrespective of family history

TP53

In most of families with LFS have been identified germline mutations in *TP53* (*Tumor protein p53*) gene. *TP53* is located in 17p13.1, has 25,767 bases and encode for a protein of 393 amino acids (<http://www.genecard.org>). *TP53* is a tumor suppression protein, consider it as “DNA guardian” for its capacity to identify when cell has a DNA damage, stop the cell cycle in order to repair the DNA and, in case that the damage is major, drive the cell thru apoptosis (Walerych, 2012). *TP53* gene significance has been supported on the others things by the

frequent occurrence of breast cancer in LFS patients. In Only the 60-80% of patient with LFS classic has been detectable germline mutation on *TP53*, while patients with LFS-L so not shown detectable *TP53* mutations. The lack of concordance among no *TP53* mutations and the presence of LFS phenotype, can be explained for possible posttranscriptional *TP53* alterations, an complete deletion, the effects of modifier genes, or the possibility of a second locus until now no identified (Malkin, 2011). Additionally *TP53* gene has a higher mutation frequency, higher than any other tumor suppressor gene in human overall. On average, *TP53* is mutated in 31% of all tumors, and in 23% of breast cancer samples, where the principal mutated protooncogene is *PI3KCA* (Walerych, 2012). In some patients had shown germinal mutations on *CHEK2* gene, which encodes for a protein kinase that functions as regulator of the cell cycle, and responds to the damage to the DNA, activating *PT53* and *BRCA1*. In the North of Europe and the United Kingdom, the variant of the gene *CHEK2* 1100delC (deletion of a cytosine at position 1100 of the gene *CHEK*) increases twice the risk for the development of breast cancer in women, and more than ten times in males; In addition to being responsible for 1% of the cases of breast cancer in women and 9% in males. These frequencies are very clear in North America, as it has been the presence of this variant in 0.3% of healthy volunteers, and in 1% of patients with breast cancer; so it is necessary to determine the contribution of the allele *CHEK2* 1100delC, in the development of cancer of the breast (Neville, 2001, Thull, 2004, Garber, 2005).

2. COWDEN SYNDROME

The Cowden Disease or syndrome of multiple hamartomas (*CS - Cowden syndrome*) (MIM #158350), described by Lloyd and Dennis in 1963, is a rare inherited genodermatosis with an autosomal dominant inheritance pattern and strong predominance of female patients (6:1), which may be fortuitous. CS is associated with both malignant lesions as benign that affect cells of the three germ layers and tissues mostly affected are tissue breast, thyroid, uterus, brain, mucocutaneous tissue and Genitourinary tract. It is estimated that 1 in every 200,000- 250,000 individuals are affected with CS, although this frequency may be underestimated due the difficulty to make the diagnosis; with an age at diagnosis ranging from 13 to 65 years. In this regards, the International Cowden Syndrome Consortium (<http://www.nccn.org>) established the diagnosis criteria in 2000, where the major (such as breast carcinoma, follicular thyroid carcinoma, multiple gastrointestinal hamartomas, macrocephaly, among other) and minor criteria (autism spectrum disorder, colon cancer, esophageal glycogenic acanthosis, mental retardation among others) are fundamental at the diagnosis process (Nagy, 2004). The penetrance in CS is related to age, since at the age of 20 years 99% of affected patients present mucocutaneous lesions, which are the most constant and characteristic findings. The risk of breast cancer in patients with CS is 25-50%, represents less than 1% of the cases of breast cancer and occurs between 38 and 46 years of age. Additionally, women with CS have a higher risk (67%) for develop benign breast disease, which include apocrine metaplasia, fibroadenomas, microcysts, adenosis, and hamartoma-like lesions with densely hyalinized collagen (Gage, 2012; Shah, 2012, 2013). Others types of cancer present in patients with CS are the thyroid cancer, typically follicular and papillary occasionally with a risk of 10%, while for cancer endometrial are 5-10%. Due to the high risk for the development of breast cancer,

patients with the SC must be monitored from an early age, starting a clinical breast examination before age 25, annual mammogram from 30 years, or in case to have a familiar with CS diagnosis and breast cancer, is important to make the first mammogram 5 years before at the age of diagnosis of breast cancer in the family, as well as an annual physical review beginning at the age of 18 years monitoring lesions in skin and thyroid, inclusive is important to include a thyroid ultrasound. Other important characteristic reported in patients with CS are craniomegaly which is the most common extracutaneous manifestation (80% incidence), gastrointestinal polyps (approximately 60-85%) with predilection from the esophagus, stomach, and colorectal structures. The small bowel is rarely involved. Polyps are usually small and <5 mm in size; cutaneous fibromas (76%), thyroid abnormalities (62%) and multiple uterine leiomyoma (40%) (Table 3) (Fistarol, 2002; Nagy, 2004; Starink, 1986). According with the mucocutaneous lesions, these include multiple trichilemmomas, oral papillomatosis, facial papules, and acral keratoses. The trichilemmomas, is defined as a benign hamartomas of the outer sheath of hair follicles, are flesh-colored smooth papules, ranging from 1 -5 mm in size and are present predominantly of the face, head and neck, close to the hairline. Other important mucocutaneous lesions described in CS include the hemangiomas, scrotal and furrowed tongue, neuromas, xanthomas, vitiligo, acanthosis nigricans, perioral and acral lentigines, and frequently the speckled pigmentation of the penis (Shah, 2012, 2013).

PTEN (Phosphatase and Tension Homolog)

In approximately 85% of CS cases has been identified mutations in the *PTEN* (Phosphatase and tensin homolog) gene, which is a gene suppressor tumor located in 10q23.31 (MIM 601728) contains 108,818 bases, 9 exons and encodes for the protein Phosphatidylinositol 3,4,5-triphosphate 3-phosphatase, consists of 403 amino acids and is a member of the super family of genes protein-tyrosine phosphatase (PTP). *PTEN* gene encodes a ubiquitously protein with dual-specificity phosphatase is due to contain a tensin like domain as well as catalytic domain similar to that of the dual specificity protein tyrosine phosphatases. Unlike most of protein tyrosine phosphatases, this protein preferentially dephosphorylates phosphoinositide substrates (www.genecards.org). This activity interferes with the progression of on G1 cell cycle through the negative regulation of PI3-kinase/Akt or PKB signaling pathway. At the same time PTEN protein regulates the mitogen-activated protein kinase (MAPK). Deregulation of these two pathways by *PTEN* inactivation or loss, increased the cell survival and uncontrolled cellular proliferation, resulting in tumor development. The mechanism that gives rise to this syndrome is loss of heterozygosis (LOH) in *PTEN* in 20-60% of cases and is explained with Knudson (double hit hypothesis) hypothesis. In the case of sporadic tumors, both alleles are normal at the moment of the conception, however subsequently have a mutation postzygotic - first hit - in one allele; subsequently a new mutation - second hit - in the other allele causes the LOH, causing a loss in the control of cell growth. In the case of hereditary tumors, the heterozygosity is present from the moment of conception and only a postzygotic mutation is necessary for the LOH (Roman, 2012). Has been reported that germline mutations in *PTEN* gene, is the most common muted gene in several cancers and are associated a number of heritable cancer syndromes, whom collectively are referred to as *PTEN Hamartoma Tumor Syndrome* (PHTS) (Pezzolesi, 2007; Tan, 2012). The PHTS includes the CS, Bannayan-Riley-Ruvalcaba syndrome [BRRS, (MIM #153480)] and Lhermitte-Duclos syndrome (Romano,

2012). According to the strict diagnostic criteria for CS, 80% of the patients presented germinal mutations in the gene *PTEN*, from which approximately 8.8% of patient are carriers of a germinal mutation and the exons 5, 7, and 8 considering as hot-spots; and all kinds of mutations including deletions, insertions, splice site mutations and large deletions have been identified in these patients. Even though many efforts had been done in order to correlate the different types of cancer or phenotype with the found mutations has not been identified (So, 2012). In such patients, it is important to discard the *Bannayan-Riley-Ruvalcaba* syndrome (MIM-#153480), since certain germinal mutations in *PTEN* have been identified in 60-65% of patients with East syndrome, by what has been considered as an allelic to the CS condition (Neville, 2001, Thull, 2004, Garber, 2005).

3. PEUTZ-JEGHERS SYNDROME

Peutz-Jeghers Syndrome (PJS) (MIM #175200), is an autosomal dominant condition, which was recognized in 1949 by Jeghers et al. as a localization of intestinal polyposis and pigmentation of the skin and mucous membranes, hence the eponym Peutz- Jeghers syndrome. The PJS has been reported around the world, affecting equally males and females; its estimate incidence is 1:8300 to 1:200,000 live births, and 25% of cases appear to be non familial or sporadic. PJS is caused by germline mutations in the *STK11* (*Serine/threonine kinase*) tumor suppressor gene; and characterized by a predisposition (20.3 increased relative risk) to developing malignant tumors in different organs, including stomach, colon, pancreas, intestine thin, thyroid, breast, lung, and uterus. The incidence of cancer in these patients has been estimated at fifteen times higher than in the general population; and the pathognomonic features are polyps hamartomatous of the gastrointestinal tract (especially in small intestine), with a specific histology, which may result in symptoms of bleeding or obstruction, being the intussusception a major complication, especially in pediatric patients (Shah, 2012, 2013). Extra-intestinal sites of PJS polyps include kidney, ureter, gallbladder, bronchus and nasal passages. The breast cancer is other important malignance in patient with PJS, affecting at 32% to 54% of patients and being the ductal and occasionally the lobular cancer the more frequent. Recent studies reported that 8% of women with PJS developed breast cancer by age 40, and 32% by age 60 (Gage, 2012; Shah, 2012, 2013). In these cases, it has been observed that the *STK11* gene expression is decreased, which correlates with a histologically high-grade, a large tumor and the presence of metastases to lymph nodes; In addition to partnering with a higher rate of relapse and worse prognosis. More features of the PJS neoplasms are of the genital tract, which include the tumor of sex cord with annular tubules (*SCTAT - Sex cord tumor with annular tubules*), followed in tumor cells of sertoli, Mucinous epithelial tumor, serous tumour and mature teratoma of ovary (Neville, 2001, Thull, 2004). Other characteristic clinical feature is the mucocutaneous hyperpigmentation, which usually is present in childhood as dark macules, and are distributed in the lips and perioral region (94%), hands (74%), buccal mucosa (66%), and feet (62%). However, the mucotutaneous hyperpigmentation also can be present in uncommon region as around the eyes, nostrils, and perianal area. Usually the lesions fade during puberty, with the exception of those on the buccal mucosa (Mishra, 2012). The cumulative risk of any cancer is 67-85% by age 70 and the cumulative risk for CRC is 3% (40 years), 5% (50 years), 15% (60 years), and 39% (70 years). The risk to age 70 for cancers of

the pancreas is 11%, utero/ovary/cervix 18%, breast 45% and lung of 17% (Shah, 2012, 2013; Mishra, 2012).

STK11 Gene

The *STK11* (Serine/Threonine Kinase) gene is the responsible of approximately 70-80% of the PJS; is located in 19.13.3, have 39,029 bases distributes in 10 exons and encode a 433 amino acid protein, STK11 (Liu, 2011). STK11 protein is part of the serine/threonine kinase family and is a well known tumor suppressor, which regulates the activity of AMP-activated protein kinase (AMPK) family members, playing an important role in several processes as cell metabolism, cell polarity, apoptosis and DNA damage response, regulating principally the expression of *p53* gene, as well as its targets genes, such as *p21*. Has been estimated a birth prevalence of mutation in STK11 at 1:25,000 to 1:280,000 (Alexander, 2011; Hemminki, 1998; Liu, 2011).

ABSTRACT

Fragile X syndrome (FXS) is the most common cause of familial intellectual disability and the most commonly known single gene causing autism spectrum disorders. The incidence varies according to the populations; it is well-accepted that 1/4,000 males and 1/6,000 females are affected, and 1/250 females and 1/800 males are carriers. The main clinical manifestations are intellectual disability, dimorphic traits and behavior disturbances. The syndrome is inherited as a dominant X-linked trait with reduced penetrance (80% for males and 30% for women). This syndrome is due to a functional loss of the *FMR1* gene product, Fragile X Mental retardation Protein (FMRP), and, in most cases it is caused by a CGG repeat expansion in the *FMR1* promoter. The repeat is from 6 to 55 CGGs long in the normal population while in patients with FXS the repeat number is over 200 CGGs (full mutation FM). This number of CGGs generally leads to methylation of the repeat and the promoter region, which is accompanied by silencing of the *FMR1* gene. The absence of the FMR1 protein, FMRP, is the cause of the intellectual disability in these patients. Individuals with 55 to 200 CGGs carry a premutation (PM). All affected children have carrier mothers (full mutation [FM] or PM) with a 50% of chance of having another affected child in future pregnancies. Female PM carriers are at risk of developing primary ovarian insufficiency (FXPOI). Elderly PM carriers (males and females) may develop a progressive neurodegenerative disorder called fragile X-associated tremor/ataxia syndrome (FXTAS). The *FMR1* gene is responsible for different disorders depending on the length of the CGG tract and the molecular mechanism. The Fragile X syndrome is due to a loss of function, and FXPOI and FXTAS are due to a toxic gain of function of the

mRNA or repeat-associated-non-AUG translation. At present, there is no treatment, although several studies are ongoing in both human and animal models.

The present and the following chapters review the current status of the wide spectrum of different pathologies related to the *FMR1* gene.

Keywords: fragile X syndrome, *FMR1* gene, CGG expansion, intellectual disabilities, autism spectrum disorder

INTRODUCTION

Intellectual disability (ID) affects 1-3% of the general population; approximately half of the ID cases have a familial origin. On the other hand the autism and autism spectrum disorders (ASD) are estimate to affect 1% of general population. The exact causes of ID and ASD are unknown, although it is thought that several complex genetic and environmental factors are involved. At present in around 50% of the cases with ID or ASD, the genetic defect remains unknown being difficult to give genetic counselling.

The first monogenic cause for these two pathologies is the *FMR1* gene which constitute the most common cause of inherited intellectual disability, developmental delay and the most commonly known single gene causing autism spectrum disorders.

This chapter it is focus on the Fragile X syndrome (FXS) reviewing the different aspects clinical, molecular basis, animal models, genetic counseling, and neonatal screening.

FRAGILE X SYNDROME

Fragile X syndrome (FXS) (FXS #MIM300624; ORPHA 908) is the most common cause of inherited intellectual disability (ID), developmental delay and is the most commonly known single gene causing autism spectrum disorders (ASD). The *FMR1* gene (Fragile X mental retardation type 1 gene) is inherited as a X-linked dominant trait with a reduced penetrance of 80% in males and 30-50% in females.

In 1943 Martin and Bell made the first description of the syndrome in males with ID and affecting more than one male in a family. The most remarkable clinical signs were moderate to severe ID, having a long face, prognatism, large ears, machroorchidism, and alterations in connective tissue as well as characteristic behavior.

The name “fragile X syndrome” was attributed to Lubs, in 1969 [1] who observed fragility at the edge of the log arm of the X chromosome. However, this fragility was only observed in a reduced number of metaphases and it was more evident in cultures in which the media was poor in folic acid.

In 1991 three groups working independently identified the gene responsible and the molecular defect [2-5]. Fragile X syndrome was the first human disease to be found to be caused by a dynamic mutation; the main mutation is a CGG expansion in the untranslated region of the first exon of the *FMR1* gene (Fragile X mental retardation type 1).

The incidence is variable depending on the population, although in general an incidence of 1/4,000 males and 1/6,000 females is well accepted, thereby considering FXS as a rare disease [6].

Clinical manifestations also vary depending on the age and sex [7-12] (Figure 1).

Prepubertal males show moderate ID with a delay in the milestones (seated, speech and ambulation) and behavioral disturbances: deficit in attention, hyperactivity, hand biting, autistic behavior, refusal to touch, shyness and gaze avoidance, repetitive movements especially of the hands and echolalia, all of which become more accentuated with age. Although the ID is usually moderate, it is not uncommon to find severe forms with an IQ between 35-55 and psychiatric disorders. In post pubertal males the physical traits are more pronounced, ID is more severe and macroorchidism is present in 80% of the cases.

Figure 1. Phenotypic appearance of two affected brothers with FXS.

The physical traits of FXS are initially quite subtle, and the first warning sign is often a delay in the emergence of language, which can be accompanied by a slight engine, hyperactive behavior, attention deficit, autistic-like behaviors such as flapping and / or hand biting, and poor eye contact. On physical examination, an elongated face with prominent chin and large and protruding ears is observed. Other relevant clinical data include joint hypermobility, especially of small joints, fine and velvety skin, being common to see many wrinkles on the palms of the hands. They usually have a high palate. Regarding the heart, the most common finding is a prolapse of the mitral valve that manifests as a mild to moderate heart murmur which is usually asymptomatic. These and other anomalies are considered mainly due to an alteration of the connective tissue.

Individuals with FXS often have no serious medical problems. Large studies have reported wide discrepancies in the prevalence of some associated medical problems. This fact is probably due to the great variability in these patients. The most prevalent medical problems are: the mitral valve prolapse, recurrent otitis media, seizures, motor tics, strabismus, sleep problems and obstructive sleep apnea. It is known that during childhood otitis (recurrent otitis media), and subsequently, sinusitis are frequent. Convergent strabismus is also often present. Many children have flat feet, but this finding tends to improve with age. Approximately 30% of patients have some degree of gastroesophageal reflux during the first year, the treatment of which depends on the severity of the reflux. In the neurological area about 15% of patients with

FXS epilepsy have some abnormal EEG findings. In a subgroup of patients with FXS the syndrome is similar to the Prader-Willi syndrome with obesity and hyperphagia phenotype.

The speech of these subjects is often repetitive; they behave shyly and look away when spoken to. In addition, they show tactile defensiveness, gaze avoidance, poor concentration, impulsivity and they sometimes present aggressive behavior. A behavioral phenotype of autism is common in males. It is usual to present stereotyped movements with both hands (shaking), self-harming biting that causes callused areas on the hands and they also show defensiveness or over-reaction to certain external sensory stimuli. Poor social skills and socio-emotional reciprocity can be added to this sometimes progressive deterioration and this can lead to a diagnosis of an autism spectrum disorder.

In general girls show attenuated clinical manifestations; mild ID and phenotypic traits are missing or minimal (big ears, joint hypermobility, elongated facies), although some cases presenting similar clinical manifestations to those of males have been reported. From 30-50% of women have ID and most have learning disabilities, behavioral disorders and communicate with shyness, presenting social anxiety, attention problems and educational delay, especially in mathematics.

The clinical diagnosis may be very difficult in girls and women due to the variable emotional and behavioral characteristics and the subtle physical traits [7-11].

Approximately 30–50% of FXS patients meet full DSM-IV-TR criteria for autism, with 60–74% fulfilling criteria for an autism spectrum disorder. Over 90% of individuals with FXS display some form of atypical behavior characteristics of autism including social interaction (e.g., avoidance of eye contact, social withdrawal, social anxiety) and repetitive and stereotyped behaviors [12-13].

The lack of function of the *FMR1* gene is the cause of FXS. This gene is located in the long arm of the X chromosome at Xq27.3, expands 17 exons and 40 kb of genomic DNA. It transcribes an mRNA of 3.9 kb. The translated protein is called *Fragile X Mental retardation Protein* (FMRP), which is necessary from early stages of development and throughout life [14].

In most cases the molecular basis of the syndrome is a dynamic mutation: an expansion and hypermethylation of an unstable CGG trinucleotide repeat located in the first exon of the *FMR1* gene [2-4]. In the general population the number of CGG repeats is polymorphic, presenting from 6 to 54 CGGs, and the adjacent CpG island, which acts as a promoter is non-methylated. This CpG island is located in the 5' untranslated region of the gene and acts as a switch depending on its methylation status. When the gene is active, *FMR1* is transcribed and translated. Alleles harboring 6 to 54 CGGs are considered normal and remain stable upon transmission.

A second class of alleles that overlaps with the upper normal range contains 45 to 54 CGGs. This range, known as the gray zone, can be stable or slightly unstable, being transmitted to subsequent generations with the possibility of expanding to a premutated allele. The clinical implications of this class of alleles remain unclear [15-16]. The next class is premutated alleles with a range of 55 to about 200 CGG repeats. In this situation, the *FMR1* gene is also transcribed and translated because the CpG island is non-methylated. Therefore, premutated carriers have normal or slightly reduced synthesis of FMRP and increased levels of mRNA (2-8 fold more than normal alleles) and they are asymptomatic for FXS. However, these carriers have a risk of having affected offspring since the number of CGG is unstable and tends to increase the CGG number in each cellular division.

People carrying permuted alleles are at risk of developing some disorders characteristic of this status such as: premature ovarian insufficiency (FXPOI), Fragile X tremor ataxia syndrome (FXTAS) and emotional disturbances, among others (see Chapters 2 and 3).

Finally, when the CGG number is over 200 repeats, these alleles are in the FM range. The CpG island and the repeats themselves are methylated and this methylation switches off the gene, blocking transcription and no protein is translated. These individuals are always affected with FXS if they are males, with only 30-50% of females being affected (Figure 2). Moreover, around 15-25% of patients show a pattern, referring to a mixture of PM and FM, which is caused by the somatic instability of the FM in early embryogenesis that can lead to retraction of the expanded repeat. Another kind of mosaicism can be observed in large expansions with incomplete methylation. The mosaicisms allow the expression of some FMRP and, in some cases, have been associated with milder ID in males.

Full Scale IQ scores were inversely correlated with the percentage of methylation and positively correlated with higher FMRP expression. These latter results point toward a positive impact on cognition for FM mosaics, with lower methylation compared to fully methylated individuals. Recent studies have suggested that low expression of FMRP may be sufficient to have a positive impact on cognitive function in these individuals. [17]. Individuals carrying the FM exhibit the classical fragile X phenotype that includes the broad spectrum of clinical manifestations described previously in this chapter and never present premutation-associated disorders such as FXPOI and FXTAS.

Figure 2. Summary of molecular aspects of the *FMR1* gene.

It is well known that some AGG are interspersed within the CGG expansion in the *FMR1* gene. The biological function of these interruptions seems to stabilize the gene during transmission and decreases the risk of DNA polymerase slippage during DNA replication. Previous studies have reported important data such as: AGG interruptions influence the stability

of the CGG repeats within the *FMR1* gene during parental transmission, the presence or absence of AGG interruptions is not correlated with the transcriptional or translational activity of the gene, and AGG interruption patterns can vary greatly between populations, but are largely inherited without change [18]

In most cases the FXS is due to a CGG repeat expansion in the *FMR1* promoter, but other *FMR1* mutations leading to a loss of function of the gene may also cause FXS or an FXS-like phenotype. Since standard molecular testing does not include sequencing of the *FMR1* coding region, the prevalence of point mutations causing FXS is not well known, although it seems that missense mutations in the *FMR1* gene might account for a considerable proportion of cases in males with FXS-related symptoms, such as those linked to ID and developmental delay. At present, the estimated frequency of point mutations is 1 to 2% of the cases of FXS [19].

The diagnosis of FXS is achieved by molecular analysis that determines the precise number of CGG in the *FMR1* gene [20]. Cytogenetic studies are currently not accepted as a diagnostic test. The quickest diagnostic method is polymerase chain reaction (PCR) using fluorescent labeled primers and subsequent analysis of the product in an image analyzer to determine the exact number of CGG repeats using small quantities of DNA. In males, the absence of PCR product indicates the presence of a pathological expanded allele.

The limitation of this technique is that it does not detect expansions of over 100 repeats and therefore does not detect large PMs or FMs and provides no information about methylation. Another limitation of PCR is that it does not distinguish between a homozygous female (both chromosomes harboring the same CGG number) and a woman with an allele in the normal range and another allele in the large PM range. These problems may be solved by conducting another PCR called Triplet-PCR (TP-PCR) which is able to identify large alleles and to distinguish between a homozygous female and a female carrying pre or full mutated alleles. Another specific PCR is necessary to detect methylation status [21-23].

These techniques are used for prenatal and postnatal diagnosis. DNA obtained from any tissue including saliva, blood, amniotic fluid, or chorionic villi can be used, thus, the choice of technique and tissue depends on the diagnostic strategy based on the clinical and family characteristics.

When an individual harboring an expansion is identified, a cascade family study is required to detect other relatives carrying pre or full mutations. In these cases precise determination of allele size and the presence of the AGG interruption are important to determine the risks of expansion in the carriers. Moreover, the status of methylation or the presence of mosaicism is relevant for genotype-phenotype correlations [24].

Finally, a test based on immunohistochemical methodology using a monoclonal antibody against the FMRP is used to detect the presence of this protein. This study may be useful in large-scale screening of the male population since males with a FM have no or a very low expression of FMRP. This test can also be useful in doubtful cases with a high PM phenotype suggestive of FXS. However, it is not useful in females, since the presence of the second normal X chromosome could modify the expression. [25-26]

In 1991, when the *FMR1* gene was cloned, Southern-blot analysis was the gold standard technique, but it is a laborious technique that requires several days of work, large amounts of DNA and gives imprecise estimates of the number of repetitions.

At present, the use of diagnostic commercial kits provided by several companies simplifies the work and ensures a safe diagnosis replacing the old techniques (Figure 3).

Figure 3. Electropherogram obtained using Amplidex Fragile X kit Asuragen. A) product from a female carrying one allele 30 CCG in normal range and the other allele with 102 CCG in permutation range, the arrows show the position of AGG interruptions and the allele size. B) Electropherogram corresponding to a PM male with 96 CCG and no AGG interruptions, were detected.

FMRP (Fragile X Mental Retardation Protein)

Cognitive impairment is caused by the absence of the FMRP in neurons. FMRP expression is widespread in neurons and spermatogonia. It is ubiquitously expressed from the early stages of development throughout postnatal life. The localization of FMRP is largely cytoplasmatic, being associated with the polyribosomes attached to the endoplasmatic reticulum and with free ribosomes at the bases of dendrites and within dendritic spines [27] FMRP plays a fundamental role in the synapses and normal development of dendrites. In healthy neurons, FMRP modulates the local translation of numerous synaptic proteins; synthesis of these proteins is required for the maintenance and regulation of long-lasting changes in synaptic strength. FMRP exerts profound effects on synaptic plasticity [28].

The *FMR1* has 17 exons with alternative splicing in exons 12, 14, 15 and 17 resulting in the expression of multiple isoforms of FMRP. The distribution of these isoforms is different according to the different brain regions except for the hippocampus and the olfactory bulb. FMRP binds to approximately 4% of all RNAs, regulating protein synthesis; and the lack of FMRP implies an excess basal translation. Approximately one third of all RNAs encoding pre- and postsynaptic proteins are targets of FMRP. This role as a transcription factor may explain the phenotypic complexity of the syndrome and the variable expression.

Animal Models for FXS

Although there are several animal models for FXS, fly and mouse models do not express the protein because the gene has been silenced, but not because of an expansion and hypermethylation.

Nevertheless, these models resemble those of affected patients, showing deficits in spatial learning, defect of prepulse inhibition of acoustic startle response, increased locomotor activity and are more susceptible to having epileptic seizures. These animal models allow the possibility of studying synaptic plasticity in many brain areas and the possibility of performing drugs trials [30-32].

For many years it was thought that PM carriers showed no clinical manifestations, only the risk of transmitting the disease to their offspring. In 1999 the presence of a PM became associated with in FXPOI women, and in 2000 a risk of late onset neurodegenerative disease, Fragile X Tremor Ataxia Syndrome (FXTAS), was associated with male and female PM carriers. Lastly, in the years 2007-2009 a range of phenotypes associated with the PM were described. It is now accepted that FXPOI (MIM#311360) and FXTAS (MIM#300623) are different from FXS and are only associated with the *FMR1* gene PM [33-37] (see Chapters 2-5).

All these associated disorders will be discussed in the next chapters. Nevertheless, it is important to highlight the importance of the PM carriers: It is estimated that more than 1 million people in the USA are *FMR1* carriers, with 20% of these subjects developing FXPOI and 40% of males and 16% of women developing FXTAS. Furthermore, 20% may present cognitive problems such as ASD (8%) and ADHD (30%).

Genetic Counseling

Although genetic counseling is discussed in detail in chapter 6, the following are the main features of this syndrome.

FXS is a genetic disorder that is inherited as a dominant X-linked trait with reduced penetrance (80% for males and 30% for women). In the general population we can find either men or women with alleles in the normal premutated or full mutated range.

Importantly, there are no sporadic cases so that whenever there is an affected child, the mother is an obligated carrier with a 50% of chance of having another affected child in future pregnancies. Members of the family in which the expansion is discarded are not at risk of presenting FXS.

Male carriers of either a PM or a FM always transmit the PM to their daughters, and thus, all carry the PM. The size of the PM is not exactly the same as the parent, and may slightly increase or decrease. Moreover, male carriers never transmit the FM. This is because only a PM and never a FM is found in the sperm. Males carrying a FM expansion transmit this to their daughters while always decreasing the CGG number to the PM range.

In conclusion, since sons inherit the Y chromosome and girls inherit the PM, male offspring are never affected by FXS.

Female carriers transmit the expanded allele to 50% of their offspring, both sons and daughters. Unlike male carriers, women tend to increase the size of the expansions in the passage from one generation to the next, so that a FM is only maternally inherited. The risk of expansion from the PM to the FM in women depends on the size of the PM and the AGG interruptions. Thus, uninterrupted and larger alleles are more likely to become a FM [16]. Indeed, whenever an allele with 100 CGG repeats is transmitted an expansion to full mutation is generated in the next generation. Women with a FM will transmit this allele mutated to 50%

of their offspring (sons and daughters), so that their offspring have a 50% risk of being affected with FXS.

It is important to highlight that despite the incomplete penetrance of the full mutated alleles in females only 50% show clinical manifestations. This fact is very important for genetic counseling especially in cases of prenatal diagnosis, when a female fetus carrying the FM is diagnosed. Nonetheless, we cannot know their phenotype.

A female carrier has different reproductive options: no offspring (adoption), ovidonation, prenatal diagnosis (amniotic fluid, corion villi or cord samples), preimplantation diagnosis or preconceptional diagnosis. (all these options will be discussed in chapter 6).

Genetic counseling in carriers of the PM should include the risk of developing pathologies associated with the PM: PM women have a 20% risk of developing a FXPOI and developing menopause before the age of 40.

PM males and females have a risk of developing FXTAS at over 50 years of age, the penetrance is 40% for males and 16% for females. [reviewed in Chapter 3, 24, 38]

At present it is advisable to request a *FMR1* test in the following cases:

- 1) Boys and girls with ID and autism, since the phenotypic characteristics are subtle in infancy it is recommended to rule out FXS in all cases of ID in whom the etiology is unclear, including a wide range of mild to profound ID, as well as developmental delays, autism, hyperactivity and other behavioral problems.
- 2) Women with infertility and / or ovarian failure before the age of 40 years, especially in cases with high levels of follicle-stimulating hormone (FSH) and if no other cause is confirmed such as ovarian cancer radiation treatment or thyroiditis.
- 3) Men and women with tremor and ataxia. Genetic testing of the *FMR1* gene is recommended in cases of cerebral ataxia with parkinsonism and intention tremor of unknown cause and cognitive decline in a person of 50 years of age.
- 4) Relatives of a diagnosed individual harboring an expansion in the *FMR1* gene. It is also necessary to perform a diagnostic "cascade", ie family studies arising from a former affection, including prenatal diagnosis in cases in which the pregnant woman is a PM or FM carrier.
- 5) Men and women who are ovum or sperm donors, due the high incidence of the PM in the general population.

Newborn Screening (NBS)

The incidence of this syndrome and its significance require its inclusion in screening programs, however, FXS is currently not included in NBS panels in any country due to its controversial particularities.

First of all, differences are observed in the diagnosis of males and females. For many years no test has been available for screening of females because of technical limitations. Secondly, there is no curative treatment for this syndrome, and finally, the screening could lead to a presymptomatic diagnosis of a neurodegenerative disease such FXTAS.

At present, the development of efficient methodologies makes FXS screening feasible for males and females. Indeed, it is possible to perform large population studies spanning the entire spectrum of *FMR1* mutation with a simple PCR.

Although no curative treatment is available, arguments in favor of NBS include the benefits of early detection that allows early intervention with good results and the possibility of cascade screening in these families and providing genetic counseling to all members.

Finally, a large number of clinical trials have been carried out regarding pharmacological interventions and new-targeted treatments will continue to be developed.

The main controversial aspect is that NBS allow the identification of PM carriers. An ever expanding number of medical disorders, although with a reduced penetrance, can occur in these individuals: ASD, ADHD, FXPOI, FXTAS, seizures, hypertension, migraines, sleep apnea, immune-mediated problems, thereby involving presymptomatic diagnosis of some diseases in very early stages of life.

This raises ethical problems which are difficult to solve. Ideally NBS for FXS should be included in NBS programs, however some ethical issues continue to make acceptance by ethical committees difficult [39].

Treatment

Although at present there is no treatment for all of these pathologies, Chapter 7 provides an update of the clinical trials on therapies for all these *FMR1* gene-related disorders and their current status.

The description of new specific treatment for experimental animal models of FXS involving therapeutic targets has allowed the discovery of drugs that are being tested and validated for treatment in humans.

The tests are intended to determine whether any of the compounds can attenuate or even normalize the clinical symptoms in patients with FXS. Until these drugs are authorized symptomatic treatments are able to control part of the disease and should be individually studied in each case to assess their effectiveness in controlling the symptoms present in each patient [40].

Table 1. Summary of the different status of the *FMR1* gene, risk of transmission and risk for the associated pathologies

CGG number	Gender	Status	Risk affected offspring	Risk develop FXPOI, FXTAS
6-45	male	Normal	No	No
	female	Normal	No	No
46-54	male	Normal	No	low
	female	Normal	No	low
55-200	male	Carrier	All daughters carrying premutation	40% FXTAS
	female	Carrier	50% FXS Depending of CGG and AGG number	20% FXPOI 40% FXTAS
>200	male	Affected FXS	All daughters carrying premutation	No
	female	30-50% Affected FXS	50% FXS	No

CONCLUSION

Fragile X syndrome is the most common cause of inherited ID, developmental delay and is a monogenic cause of autism spectrum disorders. The *FMR1* gene is responsible for different disorders: FXS (loss of function), FXPOI and FXTAS (toxic gain of function or repeat-associated-non-AUG). Although no treatment is currently available, early detection facilitates early intervention with good results and the possibility of performing cascade screening in these families and providing genetic counseling to all members.

Chapter 88

FRAGILE X-ASSOCIATED PRIMARY OVARIAN INSUFFICIENCY (FXPOI)

Maria-Isabel Tejada

GCV-CIBER de Enfermedades Raras (CIBERER), Spain

ABSTRACT

Fragile X-associated primary ovarian insufficiency (FXPOI) is among the family of disorders caused by the expansion of a CGG triplet repeat in the *FMR1* gene. FXPOI is a new clinical entity in which, carrier premutation (PM) females (with 56 to 200 CGG repeats) present early ovarian dysfunction, with menopause occurring 5 years earlier than non-carrier family members.

It has been estimated that 2-6% of all women with premature ovarian failure and a normal karyotype have a PM. Therefore, *FMR1* testing is recommended in all women with confirmed ovarian failure; i.e., cessation of the menstrual cycle during three-four months with elevated FSH levels of >30U/L.

Despite abundant literature, all authors agree that only a subset of PM carriers develop FXPOI (about 13-26%), with the precise molecular mechanisms of how the *FMR1* premutation causes FXPOI not being well understood. Nonetheless, recent studies have attempted to provide some insight into these mechanisms. This chapter summarizes some of these studies. Among these reports, the most important findings are: 1) the significant positive association of repeat size with POI, demonstrating that women with fewer than 100 repeats have an increased risk of FXPOI, and 2) the hypothesis that the *FMR1* PM may have a toxic RNA gain-of-function effect on ovarian follicle dynamics. These findings have also been demonstrated in rodent models in which the *FMR1* gene protein (FMRP) is highly expressed in oocytes which are important for folliculogenesis. Indeed, the two PM mouse models studied to date have shown evidence of ovarian dysfunction and increased expression of *FMR1* mRNA in the ovary.

Keywords: FMR1, FXPOI, ovarian dysfunction, POF

INTRODUCTION

Fragile X-associated primary ovarian insufficiency (FXPOI) is among the family of disorders caused by the expansion of a CGG triplet repeat in the *FMR1* gene. The most important syndrome caused by this expansion is Fragile X syndrome (FXS).

As seen in Chapter 1, FXS is the most common cause of hereditary intellectual disability (ID) and is one of the most frequent genetic diseases [1]. It is a dominant X-linked disease with incomplete penetrance, affecting approximately one in 2633 men in Spain [2]. This syndrome is caused by the anomalous expansion of a CGG repeat sequence in the 5' untranslated region (UTR) of the X-linked gene *FMR1* located in the FRAXA locus in Xq27.3 [3]. Transmission of this syndrome is complex since the number of CGG repeats in the population appears in four ranges: normal (N), with repeats between 6 and 45; intermediate between 46 and 54; premutation (PM) between 55 and 200; and full mutations (FM) with over 200 repeats (Figure 1). In the latter case, a second mechanism is triggered; that is, the methylation of the *FMR1* gene promoter, resulting in a silencing of thereby not allowing the production of the Fragile X Mental Retardation Protein (FMRP) which is the real cause of the syndrome [4]

Women with a PM do not generally have ID since the *FMR1* gene is not methylated (Figure 2). Nonetheless, these women have the risk of transmitting the syndrome [3], with PMs expanding to a FM in successive generations. Additionally, intermediate or grey alleles may or may not be unstable [5], with any expansion to a FM until successive generations.

Figure 1. PCR Study of CGG repeats in females. PCR products analyzed by electrophoresis through a denaturing acrylamide gel, blotting, hybridization with an oligo (CGG)₅ and visualized by autoradiography after detection with Digoxigenin and CSPD. Lanes 1 and 12: molecular DNA weight markers. Lane 2: in home ladder. Lanes 4, 8 and 11: heterozygous normal females. Lanes 3, 7 and 9: homozygous normal females. Lane 6: female with the FM and lane 10: female with the PM. (Figure from the laboratory of Dr. Tejada).

Patients with a PM were initially thought to be completely asymptomatic, however over time this belief has changed. Fragile X families have been studied since 1996 [6], showing a higher frequency of premature ovarian failure (POF) compared with the normal population. In 1999, an international collaborative study [7] reported that 16% of the carriers with a PM had POF or presented early menopause (before the age 40). Since then many groups studying FXS have confirmed this disorder in PM carriers [8-10].

Over the years POF resulting in early menopause has been confirmed as a phenotypic characteristic of PM carriers although only about 13-26% of PM carriers actually present this disorder (1:650 females) [11]. On the other hand, an estimated 2-6% of all women with POF and a normal karyotype have a PM [8,12]. Interestingly, FM carriers do not present ovarian dysfunction. To the contrary, the loss of normal ovarian function has been demonstrated in women with intermediate alleles [11,13], and it has even been suggested that women with alleles with more than 30 repeats have a higher risk of having a diminished ovarian reserve [14].

Figure 2. Southern blot analysis. DNA digested with EcoRI and EagI. Hybridization with the StB12.3 probe visualised by autoradiography after detection with Digoxigenin and CSPD. Lanes 1 and 3: normal males. Lanes 2, 5 and 7: females with the PM. Lanes 4: an affected FM male and lane 6: normal female. (Figure from the laboratory of Dr. Tejada).

In 2007, the National Fragile X Foundation defined the term “FXPOI” [15] as a condition in which there is a primary ovarian insufficiency (POI) with menopause occurring at 40 to 45 years of age in association with a PM of the *FMR1* gene [16]. The term –FXPOI– was considered more appropriate than Premature Ovarian Failure (FXPOF). Indeed from the point of view of reproductive counselling, women with FXPOI are able to become pregnant following periods of ovarian failure while those with POF are not. Nonetheless, these pregnancies may lead to a child with FXS.

DEFINING THE DISORDER

Primary ovarian insufficiency is also known as premature menopause, premature ovarian failure, hypergonadotropic amenorrhea and hypergonadotropic hypogonadism, conditions occurring due to chemotherapy, radiation or surgery [17]. At present, the term POI is increasingly used because it better describes impaired ovarian function as a continuum rather than a specific endpoint [18]. FXPOI may be transient or progressive, and usually results in eventual premature menopause. Menopause is the permanent cessation of menses that normally occurs at an average age of 50 years, whereas POF and POI generally describe a disorder consisting of amenorrhea, elevated menopausal level gonadotropins and sex steroid deficiency in women less than 40 years old.

In 2004, Welt and colleagues [19] reported that PM carriers have early ovarian aging. Since then, many different publications have appeared [reviewed in 16,20] demonstrating that FXPOI is the result of low ovarian reserves, which is manifested as a decrease in fertility. On comparison with normal control women FXPOI is associated with increased levels of some hormones, especially the follicle stimulating hormone (FSH) and with the decreased duration of one of the menstrual cycle phases, the so-called follicular phase.

Similarly, Anti-Müllerian hormone (AMH) levels, a marker of the growing cohort of small follicles, have been demonstrated to be lower among PM carriers compared with non-carriers of all ages (18 to 50 years). Overall, in women with a PM it seems that AMH is a good indicator of ovarian senescence, being even better than FSH concentrations [16, 20].

In short, FXPOI is a new clinical entity in which PM females (with 55 to 200 CGG repeats) present early ovarian dysfunction, with menopause occurring 5 years earlier than non-carrier family members.

DIAGNOSIS AND GENETIC COUNSELLING

FMRI testing is recommended in all women with confirmed ovarian failure: cessation of menstrual cycles during three-four months with elevated FSH ($>30\text{U/L}$) in two determinations carried out within a two-month period and with lower than normal AMH levels. Unfortunately, standardized diagnostic criteria for POI have not yet been established. Nonetheless, determination of estradiol (E2) and prolactine levels in serum may help in establishing the diagnosis [21]. The screening history should also focus on a family history of early menopause, autism and ID. However, in cases in which the diagnosis of ovarian failure is not clear (women with fertility concerns but normal or erratic cycles and women with occult forms of POI) but which present elevated FSH levels, *FMRI* testing is also recommended [20].

This recommendation is especially important in women following fertility treatments since carriers of a PM may have children with FXS [22].

In conclusion, *FMRI* testing is undoubtedly important in women with reduced fertility from the point of view of Genetic Counseling. Nonetheless, CGG studies are also indicated in other women, such as in the case of egg donors due to the high frequency of PMs and intermediate alleles in the population [23].

MECHANISMS PRODUCING FXPOI

Despite abundant literature, all authors agree that only a subset of PM carriers develops FXPOI, however, it remains unknown why some present POI while others do not.

The precise molecular mechanisms of how the *FMR1* premutation causes FXPOI are not well understood, although recent studies have attempted to provide some insight into these mechanisms. Among these reports, a significant positive association of repeat size has been demonstrated with POI and it has been found that women with fewer than 100 repeats have an increased risk of FXPOI, although this relationship is not linear [10, 24]. In this range, it seems that women with 80 to 100 repeats have the highest risk of presenting altered cycle traits and subfertility [20]. Carriers of both smaller and larger PM repeat sizes also present ovarian insufficiency, albeit with a lower frequency. Furthermore, a loss of normal ovarian function has also been demonstrated in women with intermediate alleles [11].

A few studies have described the CGG structure in women with FXPOI, that is, the number of AGG interruptions (See Figure 3 Chapter 1). AGG interruptions have been shown to decrease the risk of the expansion of a PM to a FM, and in one small study it was shown that women with POI and intermediate alleles had no AGG interruptions [13]. Nevertheless, a study by our group [25] did not confirm this observation.

Others studies have postulated the hypothesis that the *FMR1* PM may have a toxic RNA gain-of-function effect on ovarian follicle dynamics. In fact, studies on *FMR1* gene expression in males with the PM showed elevated *FMR1* mRNA levels, and this increased transcriptional activity appeared to be positively correlated with CGG repeat size and with the manifestation of FXTAS [26, 27]. Similarly, the effect of the CGG repeats on the mRNA levels was statistically significant in patients with POF, but not in those without POF (Figure 3) [10], demonstrating RNA gain-of-function toxicity in PM carrier women.

However, the relationship between molecular status and phenotype is much more complex in women, in whom the activation ratio of the X chromosome must be considered [9]. Nevertheless, levels of the *FMR1* transcript among female premutation carriers have been demonstrated to be increased, with the relationship between mRNA levels and repeat size being nonlinear, with a cut-off at 100 repeats [10]. It has also been suggested that due to skewed X inactivation mRNA levels tend to normalize in females with an increase in the number of CGG repeats [9].

Indeed, since the *FMR1* gene is located on the X chromosome, it has been proposed that X-chromosome inactivation may play a role in the possible development of FXPOI. However, the first study by Murray et al., [28] reported no significant effect on comparing FXPOI, *FMR1* repeat size and X-chromosome inactivation patterns, having been confirmed by other studies [20].

Regarding FMRP levels, some studies have described increased FMRP levels in the range of 80 to 89 repeats in carrier males [29]; however, similar studies have not been carried out in women [20].

In relation to the parental origin of the PM allele, Hundscheid and co-workers (2000) [30] suggested a role for imprinting on finding a significant effect between FXPOI and parental origin. Nonetheless, further studies have failed to confirm these findings [8].

Figure 3. Relation between the CGG repeats and mRNA levels depending on the POF status of the patients. The effect of the CGG repeats on the mRNA levels was statistically significant ($p=0.0437$) in patients with POF, but not ($p=0.0724$) in patients without POF (Figure from Tejada et al., 2008 [10]).

Finally, FXPOI may not only depend on the PM allele but also on other modifier genes and environmental factors. Hunter et al., [31] showed significant familial aggregation of age at menopause, providing evidence of the presence of additional genes influencing and interacting with FXPOI. The identification of additional genes involved in ovarian function is therefore a new step in future studies. In this regard, Allen and co-workers (2014) [32] performed a study of a candidate gene using whole genome sequencing (WGS) to identify possible variants that may influence the onset of FXPOI. Although no conclusions could be drawn, they did find some potentially damaging variants that deserve further investigation.

In short, to date neither the exact etiology of FXPOI nor the cause of the variation in phenotype is understood, and thus, additional studies are clearly needed.

MOUSE MODELS

Non-invasive methods to study the mechanisms of the PM in ovarian function in humans are currently not available. This is why the development of model systems is necessary to enhance the knowledge of FXPOI. Only recently have mutation vertebrate (mouse and rat) and

invertebrate (*Drosophila melanogaster*) models been used to study ovarian function and the results published to date indicate the value of studying the etiology of FXPOI. The recent work by Sherman and colleagues (2014) [33] reviews and summarizes everything published so far.

Rodent models have basically shown that FMRP is highly expressed in oocytes in which this protein is important for folliculogenesis. The two PM mouse models studied to date [34,35] have showed evidence of ovarian dysfunction and, together, suggest that the long repeat in the transcript itself may have some pathological effect very different from any effect of the toxic protein.

Furthermore, ovarian morphology in young animals appears normal and the primordial follicle pool size does not differ from that of wild-type animals. However, there is a progressive premature decline in the levels of most follicle classes. Observations also include granulosa cell abnormalities and altered gene expression patterns. In this line, in a rat model, Ferder and collaborators (2013) [36] found changes in *FMR1* expression during follicle maturation, both at the protein and mRNA levels. Indeed, in all PM mouse models, increased expression of *FMR1* mRNA has been described in the ovary.

Premutation model systems in non-human primates and those based on induced pluripotent stem cells have shown particular promise and will complement current models, although definite conclusions remain to be established.

Fly models have shown to be very useful because of the relative ease of model construction compared with other model systems. For example, *Drosophila* germ line stem cells have been used as a model to show that FMRP can modulate the fate of stem cells [37]. This study suggested that both the reduction of FMRP and expression of PM CGG repeats could have detrimental effects on fly ovary and stem cell maintenance.

Among other ideas in progress, Sherman and co-workers (2014) [33] have also highlighted the possibility of testing the effect of genetic modifiers on the ovarian phenotype. This could be valuable for not only understanding the pathogenic mechanism, but may also shed light on human homolog genes of which may contribute to the variable penetrance of FXPOI.

In summary, all these studies mentioned above are very promising but definitive conclusions remain to be drawn. Further comparisons of all of these models are still needed to gain insight into the etiology of ovarian dysfunction.

CONCLUSION

FXPOI is a new clinical entity in which carrier PM females of the *FMR1* gene may present early ovarian dysfunction with menopause occurring at approximately 40 years of age. To date neither the exact etiology of FXPOI nor the cause of the variation in phenotype is understood. New technologies with next generation sequencing and studies in animal models are very promising, but definitive conclusions remain to be drawn, thereby requiring further investigations in this pathology.

ABSTRACT

Fragile X-associated tremor/ataxia syndrome (FXTAS) is a late-onset inherited neuropsychiatric degenerative disorder that occurs predominantly in male carriers of the *FMR1* premutation (55-200 CGG repeats). *FMR1* premutation is relatively frequent in the general population, affecting approximately 1 out of 800 males and 1 out of 250 females, and leading to symptoms of FXTAS in up to 1 in 3,000 men older than 50 years. Clinical symptoms in FXTAS patients usually begin with an action tremor. After that, different findings including ataxia (balance problems with frequent falling), and more variably, loss of sensation in the distal lower extremities and autonomic dysfunction (e.g., impotence, hypertension, and loss of bowel and bladder function), may occur, and gradually progress. Molecular mechanism leading to FXTAS is distinct from the *FMR1* silencing mechanism and/or a deficit in FMRP operating in fragile X syndrome. Individuals with *FMR1* premutation alleles have markedly elevated levels of expanded CGG-repeat *FMR1* mRNA, which is thought to have a toxic gain-of-function. Since 2001, when FXTAS was first described, the advancement of our understanding of the clinical phenotype as well as the molecular pathophysiology has occurred very quickly. The aim of this chapter is to present the most recent advances in the current knowledge of FXTAS.

Keywords: *FMR1*, FXTAS, ataxia, tremor, mRNA toxicity

INTRODUCTION

Fragile X-associated tremor/ataxia syndrome, FXTAS (OMIM# 300623) was identified in 2001 by Hagerman and co-workers as a late-onset neurodegenerative disorder [1]. It took more than 10 years after the *FMR1* gene identification to recognize FXTAS as a *FMR1* premutation associated phenotype. One explanation for this is that the movement disorder experienced by older carriers, who were thought to be clinically normal, was not associated with the fragile X syndrome (FXS) (a childhood disorder) affecting children. Mothers of FXS children, being seen in clinics, were often expressing concerns about their fathers (*FMR1* premutation carriers) who were experiencing problems with hand tremor and unsteady gait. When Hagerman and co-workers evaluated these male carriers they found that they were more likely to develop, from 50 years onwards, a stereotyped clinical picture characterized by unsteadiness while walking and action tremor in both hands. Both symptoms used to follow a progressive course, and were often accompanied by progressive cognitive and behavioral disturbances [1]. Although, FXTAS was firstly identified among older *FMR1* premutation male carriers, to date it is well established that it also affects females. Nevertheless, it has been suggested that it occurs less frequently and that the phenotype is milder with older age at onset [1, 2]. An explanation for this difference is the presence of a second normal allele and a random X-inactivation of the premutated one; however, there may be additional sex-specific effects that reduce penetrance among females [3].

FXTAS penetrance is not complete; meaning that not all *FMR1* premutation carriers develop FXTAS. It is largely dependent on carrier age, with symptoms typically seen in 30% of males by the age of 50 and in 50% of males older than 70 years. Moreover, there is significant variability in the progression of neurological dysfunction [2-5].

The description and characterization of FXTAS syndrome is of great interest to the population, because the prevalence of *FMR1* premutation in the general population is relatively high. In fact, it is estimated that 1 in 800 to 1,200 males and from 1 in 250 to 400 females are carriers of a *FMR1* premutation allele [6-8]. Although the contribution of FXTAS to the morbidity and mortality of the aging population requires further study, the disorder is likely the most common single-gene form of tremor and ataxia in the older adult population. Taking into consideration the prevalence of *FMR1* premutation in the general population, the prevalence of FXTAS might be estimated in ~1/3,000 males aged over 50 years of age (~1/10,000 males of all ages) [3].

FRAGILE X-ASSOCIATED TREMOR/ATAXIA SYNDROME

FXTAS Clinical and Cognitive Overview

Originally FXTAS was clinically described as a motor disorder with core features including kinetic tremor and cerebellar gait ataxia. Clinical symptoms of FXTAS syndrome appear in patients in their 50s and they usually begin with an action tremor. Additional clinical features include peripheral neuropathy (60%), impotence (80%), bowel and bladder dysfunction (30-55%), erectile dysfunction, loss of sensation in the distal lower extremities, hearing loss and dysphagia [reviewed in 9].

Over the last years, the clinical spectrum of the disease has expanded and new data have evidenced that progressive cognitive decline, with a gradual progression to dementia in some individuals, and neuropsychological problems are common among FXTAS patients [10-16]. Several studies comparing psychiatric symptoms in FXTAS with matched comparison groups have been performed. Overall, they describe that the neuropsychiatric phenotype of FXTAS is characterized primarily by poor performance on measures of executive function, working memory, information processing speed, and fine motor control. While attention and language function may also be affected in patients with FXTAS, there is limited evidence regarding the affection of visuospatial function. Secondary behavioral features may include depression, anxiety, and obsessive-compulsive symptoms. Finally all evidences concluded that this profile is consistent with a dysexecutive fronto-subcortical syndrome [10, 16, 17].

FXTAS clinical symptoms tends to progress from mild ataxia and/or tremor to a disabling condition impacting on motor daily activities, thinking, and social skills that seriously compromise patients' quality of life.

Because of the variety of clinical symptoms in FXTAS, genetic testing for FXTAS must be considered in any patient (male and female) with ataxia developing after the age of 50. Diagnostic testing consists of determining *FMR1* CGG repeat size by polymerase chain reaction (PCR) technique, which nowadays is a highly sensitive test performed in many laboratories.

FXTAS Neuroimaging and Neuropathological Profiles

Magnetic resonance imaging (MRI) of the brain was obtained in FXTAS patients searching for specific features. Individuals with FXTAS demonstrate moderate to severe generalized brain atrophy with ventricular enlargement, cerebellar atrophy, and subcortical and/or pontocerebellar white matter lesions [18, 19]. This pattern frequently includes hyperintensities in the cerebellar white matter and middle cerebellar peduncles on T2-weighted images, called the "MCP sign" [19]. These characteristic findings, initially described on conventional MRI, were classified into two categories -major and minor criteria-, and proposed, together with clinical findings, as diagnostic criteria for FXTAS (Table 1) [18].

Cerebellar abnormalities were confirmed by post-mortem histological studies that identified several neuropathological features, including Purkinje cell decreases and spongiform changes [20, 21]. Significant loss in whole cerebellar volume has been revealed in both male and female patients with FXTAS [22, 23].

Although the MCP sign is considered a major radiological feature of FXTAS, it has been also reported in patients with other forms of adult-onset cerebellar ataxia, thus resting specificity for FXTAS [24]. As more evidence among FXTAS individuals developing neurological features is being gained, the spectrum and variability of MRI features becomes broader and the potential usefulness of neuroimaging in providing insight in FXTAS becomes more evident [reviewed in 25]. Furthermore, with the advent of high field strength MRI as well as more sophisticated postprocessing tools the understanding of FXTAS neuropathological profile becomes wider. In this context, Hashimoto and co-workers [14] assessed focal changes of grey and white matter density in the brain of *FMR1* premutated carriers using voxel based morphometry method. In this study, patients with FXTAS demonstrated a distinct pattern of grey matter volume loss, involving multiple cortical and subcortical regions. This included

different parts of the cerebellum, as well as of the medial surface of the brain, including the dorsomedial prefrontal cortex, anterior cingulate and precuneus. Additional volume loss was seen in the lateral prefrontal cortex, orbitofrontal cortex, amygdala, and insula. More interestingly, there were significant correlations between grey matter loss in different brain regions, behavioral scales, and CGG repeats [14].

Table 1. Clinical criteria for FXTAS

Examination and Degree	Observation
Radiological:	
Major	MRI white matter lesions in MCPs and or brain stem
Minor	MRI white matter lesions in cerebral white matter
Minor	Moderate-to-severe generalized atrophy
Clinical:	
Major	Intention tremor
Major	Gait ataxia
Minor	Parkinsonism
Minor	Moderate-to-severe short-term memory deficiency
Minor	Executive function deficit

Inclusion criterion: CGG repeat number between 55 and 200.

Note. Data described by [18].

These radiologic features have been histologically confirmed in FXTAS post mortem cases. Early neuropathological, post mortem studies of the brain of patients with FXTAS revealed intranuclear inclusions in neurons and astrocytes throughout the cerebrum and brainstem, being most numerous in the hippocampal formation [20]. These inclusions appear as eosinophilic, hyaline, refractile, 2-5 μm diameter, round to ovoid bodies that show positive reactivity with antibodies against over 20 different proteins including ubiquitin, $\alpha\beta$ -crystallin, lamin A/C, hnRNP A2, myelin basic protein, DNA repair-ubiquitin-associated HR23B, and Sam68, among others [26-28]. The inclusions are PAS, silver, amyloid, and α -synuclein negative [20, 21]. Additionally, the *FMR1* mRNA but not the FMRP has been found contained within intranuclear inclusions [27, 29].

Although Purkinje cells rarely have inclusions, there is neurodegeneration in the cerebellum, with marked Purkinje cell loss, axonal swelling, and gliosis. Apart from reduced Purkinje cell number, additional neuropathological features present in FXTAS include, axonal torpedoes, and prominent cortical and subcortical white matter pathology [20, 21].

Recently, a broad distribution of intranuclear inclusions in non-central nervous system has been observed in *FMR1* premutation carriers with FXTAS [28]. Inclusions were found in somatic organs such as the endocrine organs, gastrointestinal tract, heart, and kidney [28]. Although these findings are consistent with the expanding range of co-morbid medical features reported in FXTAS (see chapter 5), intranuclear inclusions are not the cause of these conditions.

Nowadays FXTAS is considered as a new class of inclusion disorder. However there are several unclear aspects such as the cellular processes underling inclusion formation and whether the inclusions are themselves toxic or simply reflect underlying cellular dysfunction.

Molecular Genetics Overview

FXTAS is an allelic disorder to the FXS, and therefore should be considered as a distinct neurodegenerative disorder. Although both disorders are caused by expansions of the CGG repeat element found in the *FMR1* gene, the molecular mechanism leading to FXTAS is distinct from the *FMR1* silencing mechanism and/or a deficit in FMRP operating in FXS. In premutated patients the *FMR1* gene is rarely silenced and FMRP levels are generally normal or only slightly lowered [3]. The only known molecular abnormality among *FMR1* premutation carriers is the presence of markedly elevated levels (~2-8 fold) of *FMR1* mRNA.

The increased transcriptional activity of the *FMR1* gene seems to be positively correlated with the size of the CGG repeat. That is, CGG repeats in the upper range (100-200 CGG) result in average 5-8 fold elevation, whereas CGGs in the lower range (50-100 CGG) result in an average 2-fold elevation [30-33]. Although the precise mechanism for this overexpression is unknown, several possible mechanisms have been postulated. A feedback mechanism suggests that the cell attempts to compensate for reduced levels of FMRP by increasing the amount of available *FMR1* transcript [reviewed in 34, 35]. Alternatively, it is likely that the increasing length of the CGG repeat near the *FMR1* promoter proportionally opens the chromatin, allowing more ready access to transcription factors [36]. The presence of these elevated levels of abnormal (expanded CGG repeat) *FMR1* mRNA led to propose an RNA “toxic gain-of-function” model for FXTAS, in which the mRNA itself, with the abnormal CGG repeat tract, is causative of the neurological disorder [1, 3, 18, 20]. Animal and cell-based studies have demonstrated that the sole expression of expanded CGG repeats is necessary and sufficient to cause pathology similar to human FXTAS [37-40], and thus indicate that the expanded CGG repeats in RNA are the likely cause of the neurodegeneration in FXTAS.

In particular, the hypothesis of a RNA toxic gain-of-function suggests that CGG repeat *FMR1* mRNA recruits RNA-binding proteins and other proteins through direct RNA–protein interactions, but probably also through indirect protein–protein interactions. The sequestration of these proteins is also thought to prevent normal function leading to downstream alterations [34, 41].

Nowadays, several proteins have been identified that interact with the CGG repeat and might be potential mediators of downstream cellular dysregulation [reviewed in 42]. Table 2 summarizes candidate protein mediators of the CGG-repeat mRNA toxicity. The protein components of FXTAS inclusions fell into eight major functional categories, including: histone family; intermediate filament; microtubule; myelin-associated proteins; RNA-binding proteins; stress-related proteins; chaperones and ubiquitin-proteasome-related proteins [reviewed in 34]. Although most of them have been found to localize with ubiquitin-positive inclusions in CGG-expressing *Drosophila*, knock-in (KI) mouse model and FXTAS patients, they are not found to be sequestered by expanded CGG repeats and consequently they are not expected to lose their functions in FXTAS patients [43]. The lack of a principal protein species in the inclusions is not surprising, since there is no known abnormal protein product associated with FXTAS. In particular, the protein product of the *FMR1* gene, FMRP, is not structurally abnormal, as the expanded CGG repeat is located in a non-coding portion (5'-UTR, 5'-untranslated region) of the gene.

A striking characteristic of CGG expanded repeats is that they form dynamic intranuclear RNA aggregates that enlarge with time, resulting in the formation of giant inclusions. Continuous enlargement of CGG RNA aggregates suggests that these repeats may constantly

recruit proteins, implying a founding RNA-protein interaction event that would subsequently trap other proteins through indirect RNA-protein or protein-protein interactions [43].

Table 2. Candidate proteins involved in mediating the RNA-triggered pathogenesis

Protein	Function	Evidences	Reference
Sam68	Splicing modulator	- its ablation in mouse leads to motor dysfunction - is partially sequestered and functionally inactivated in FXTAS patients	[43, 44]
Pur α	Single-stranded cytoplasmatic DNA and RNA binding protein	- mediates neurodegeneration in <i>Drosophila</i> and mouse - binds CGG repeats in both mammalian and <i>Drosophila</i> brains - found to be present in the inclusions of FXTAS brain tissues - overexpression can alleviate neurodegeneration in FXTAS fly model	[45]
hnRNP A1 hnRNP A2/B1	RNA binding proteins	- assists mRNA dendritic transport in <i>drosophila</i> and cultured rat neurons - binds CGG repeats in both mammalian and <i>Drosophila</i> brains - found to be present in the inclusions of human FXTAS brain tissues - overexpression suppresses the phenotype of the CGG transgenic fly	[27, 46, 47]
DROSHA-DGCR8	microRNA nuclear processing complex	- binds to expanded CGG repeats - microRNA dysregulation in human FXTAS brain tissue - overexpression of DGCR8 rescues neuronal cell death	[48]
ubiquitin	post-translational modification	- present in the inclusions of human FXTAS brain samples	[27]
α B-crystallin	heat shock protein	- present in the inclusions of human FXTAS brain samples	[27]
Lamin A/C	intermediate filament proteins	- present in the inclusions of human FXTAS brain samples	[27]
MBP	myelin basic protein	- present in the inclusions of human FXTAS brain samples	[27]

Proteins recruited through protein-protein interactions have not been listed (e.g., CUGBP1, Rm62, Hsp70).

The current hypothesis contemplates that the CGG-repeat expansion drive to cellular dysregulation that cause eventual cell death. Mitochondrial abnormalities [49, 50], altered calcium regulation [51], altered lamin A nuclear architecture [52], and reduced telomere length [53], have been described as potential downstream pathways that could mediate cellular dysregulation [reviewed in 54].

Although FXATS is defined as a late-onset disorder, recent findings prompt to a process that begins in early development. Abnormalities of neuronal morphology and network activity as well as alerted calcium regulation have found in late embryonic and neonatal premutation mouse model [51, 55-57]. This observation suggests that there is an early developmental impairment that precedes cellular loss of viability, which somehow might explain the broad clinical phenotype associated with the *FMR1* premutation (See chapter 5).

As exposed in this chapter, there are several evidences that support the RNA-toxic-gain of function model for FXTAS. However, at least two additional mechanisms of toxicity have been described [reviewed in 58]. The first one compromises the translation in all reading frames of expanded CGG repeats in the absence of an ATG initiation codon (non-AUG initiated translation, RAN), leading to the production of homopolymeric protein. In particular, Todd and co-workers [59] demonstrated the existence of one particular CGG RAN translation product (polyglycine), which directly modulates CGG-associated pathology in two distinct model systems. Therefore on the basis of their observations it is suggested that a protein gain-of-function may also occur in cells of patients with FXTAS. Secondly, an antisense *FMR1* mRNA and a number of long noncoding RNAs have been identified within/near the *FMR1* gene [60-62]. Although the relevance of these transcripts is not fully understood they might have important functions and/or modulate certain aspects of FXTAS [reviewed in 58].

Overall, these observations raise the possibility of different or additive/synergistic molecular mechanisms contributing to the pathogenesis of FXTAS.

Even though the understanding of molecular basis of FXTAS has evolved over the last years and many different aspects of its pathogenesis have been unraveled, we still do not know how to link all of them. Furthermore, there is the puzzling issue of the incomplete penetrance. Additional genetic and/or environmental factors might play a key role and might be related with the emergence of FXTAS clinical symptoms. In this scenario, further research is needed since the better understanding off all these aspects might help to prevent or delay the onset of the syndrome.

FXTAS Treatment

Currently, there is no specific targeted treatment for patients with FXTAS. The present medical management of patients with FXTAS is limited to medications that targets specific symptoms such as tremor, ataxia, mood changes, depression, cognitive decline and/or dementia [reviewed in 9, 54]. Although neurological rehabilitative therapies have not been studied specifically in FXTAS they should be considered in treatment. Furthermore, occupational and physical therapy might also be beneficial and improve strength and stability in those with tremor, gait and balance deficits.

RNA toxicity initiates brain changes well before the onset of FXTAS. Typically, the age of onset of FXTAS is in the early 60s, and it presents with onset of tremor. However, as described before in this chapter different findings suggest that asymptomatic changes associated with the pathological changes of FXTAS exist before the onset of tremor or ataxia. Additional genetic and/or environmental factors might be necessary to precipitate FXTAS symptoms. In this regard, chemotherapy, prolonged surgery with general anesthesia or exposure to toxins, genetic predisposition to mitochondrial dysfunction, coexistence with

another disease such as multiple sclerosis or Alzheimer's disease have been described as factors that can precipitate FXTAS clinical manifestations [reviewed in 54].

On the basis of these observations, FXTAS treatment should envision two approaches; a direct one addressed to eliminate the expanded CGG-repeat mRNA and a prophylactic one, protecting neurological cells from neurotoxic chemicals.

CONCLUSION

Since 2001, when FXTAS was first described, the advancement of our understanding of the clinical phenotype as well as the molecular pathophysiology has occurred very quickly. Nowadays, FXTAS clinical description includes a much broader symptoms spectrum than the initial core features of intention tremor and gait ataxia. Furthermore, since the observation of increased expression of *FMR1* mRNA, a RNA toxicity hypothesis and other possible pathological mechanisms have been proposed with multiple studies supporting them. Although a lot has been achieved in this short period of time, further work is necessary to link and fully understand all the molecular mechanisms that might play a role in FXTAS pathology. The better understanding of these processes should also shed light on therapeutic approaches that will combat not only neurodegeneration but also the rest of symptoms. Finally, as the prevalence of *FMR1* premutated alleles is relatively high in general population, FXTAS may represent one of the more common monogenic causes of tremor, ataxia, and dementia. For this reason, it is probably that many carriers with FXTAS are being seen by a clinical specialist without awareness of the underlying genetic basis for the symptoms. The early diagnosis of those patients not only benefits themselves but also the rest of the family that should be advised for the FXS.

ABSTRACT

This chapter describes the psychopathological alterations of the different phenotypes associated with the *FMR1* gene. Fragile X patients present enormous functional impairment with a behavioral phenotype of hyperactivity and impaired attention, marked anxiety, with poor eye contact, affective lability, aggression, self-injurious behavior and autistic features. Since its first description the basic formulation of the fragile X behavioral phenotype has remained intact to the present day, with substantial confirmation of these basic findings in subsequent studies. Autism is one of the most recognized and severe behavioral abnormalities observed in males with fragile X syndrome (FXS) and this syndrome is the leading known monogenic cause of autism, accounting for approximately 5% of autism cases. Approximately 30–50% of FXS individuals meet full Diagnostic and Statistical Manual of Mental Disorders DSM-IV-TR criteria for autism with 60–74% fulfilling criteria for an autism spectrum disorder (ASD). Attention deficit and hyperactivity disorder (ADHD) is the most common diagnosable condition in FXS patients, with most males meeting formal criteria at some point in their lives. In children with FXS, ADHD is reported to be characterized by more inattentiveness, restlessness, fidgetiness and impulsivity. However, affective symptoms can be severe and disruptive, and are a common target for psychopharmacologic intervention. Several clinical subgroups present a higher risk for presenting anxiety outcomes, including children with FXS. Males with FXS display a broad range of anxiety symptoms, but these symptoms often do not fit into the established categories of major anxiety disorders employed by the DSM.

Regarding individuals carrying a premutation there is a growing body of literature suggesting that neuropsychiatric features of fragile X-associated tremor/ataxia syndrome (FXTAS) follow a fronto-subcortical pattern with primary impairments in executive function and increased vulnerability to mood and anxiety disorders. Increased rates of psychiatric symptoms may represent early markers of neurodegenerative diseases and have also been reported among *FMR1* premutation carriers without FXTAS. On the other hand, several studies have reported an excess of intermediate *FMR1* alleles in patients with cognitive and/or behavioral phenotypes. Numerous studies have investigated neuropsychological phenotypes among premutation allele carriers in women, but no definitive profile has been achieved. An increased risk of anxiety and mood disorders among premutation allele carriers has not been established, although they seem to be more common in these subjects than in controls.

Keywords: ASD, *FMR1*, hyperactive disorders, mood disorders, anxiety disorders

INTRODUCTION

The fragile X Syndrome (FXS) is associated with a complex but relatively consistent psychiatric phenotype and provides the enticing possibility of understanding a complex neuropsychiatric disorder at the synaptic, molecular, and genetic levels. This chapter describes the psychopathological alterations of the different phenotypes associated with the different status of the *FMR1* gene: FXS (>200 CGG), premutated individuals (55-200 CGG) and intermediate alleles (45-54 CGG). In 1984, Fryns [1] studied a large population of fragile X males, describing a behavioral phenotype of hyperactivity and impaired attention, marked anxiety with poor eye contact, affective lability, aggression, self-injurious behavior (especially the characteristic hand biting), and autistic features reported as repetitive, perseverative and stereotypic behaviors. This basic formulation of the fragile X behavioral phenotype has remained intact to the present day, with substantial confirmation of these basic findings in subsequent studies.

FRAGILE X SYNDROME

Fragile X patients suffer maladaptive behaviors and emotional disturbance with an enormous functional impairment; symptoms are a frequent reason for families to seek treatment and can lead to institutionalization in more severe cases.

Autism Disorders

Autistic disorder is the most debilitating subgroup of a larger category known as pervasive developmental disorders (American Psychiatric Association) characterized by impairment in social interaction and verbal and non-verbal communication, and restricted, repetitive and stereotypic patterns of behavior, interests and activities. Although there is considerable variability in individual symptoms, core deficits in social communication and restricted and repetitive behaviors are hallmarks of the disorder [2]. FXS is the leading known monogenic

cause of autism, accounting for approximately 5% of autism cases [reviewed in 3] and autism is one of the most recognized and severe behavioral abnormalities observed in males with FXS [4-8]. In individuals with the full mutation, approximately 30–50% meet full DSM-IV-TR criteria for autism with 60–74% fulfilling criteria for an autism spectrum disorder (ASD) [9-13]. Over 90% of individuals with FXS display some form of atypical behavior characteristic of autism, including social interaction (e.g., avoidance of eye contact, social withdrawal, and social anxiety) and repetitive and stereotyped behaviors [14]. Co-morbid FXS and autism are indicative of worse developmental outcomes [15-17], and greater impairment in cognition and adaptive behavior skills are more severe aberrant behavior than FXS without autism [18]. It has been suggested that autistic behaviors increase slowly but significantly over time, as do associated social avoidance behaviors [19].

The main dilemma arises when considering the pathogenesis of clinical autism spectrum in patients diagnosed with the FXS. Some authors consider that the clinical autism spectrum in these patients is a consequence of pathophysiological alterations resulting from the mutation of the *FMR1* gene, while other authors consider that this clinical autism spectrum in these patients has an etiopathological mechanism similar to idiopathic autism. These different points of view are generated due to the fact that diagnostic criteria for autism spectrum disorders are purely clinical.

Likewise, Harris (2011) [20] has proposed a focus on brain-behavior relationships targeting advancement of behavioral phenotyping in neurogenetic disorders precluding the application of DSM-IV diagnostic behavioral criteria to identify disorders such as FXS. He proposed that FXS is a neural model and phenocopy of autism and should not be considered a genetic model for autism. On the other hand, a number of investigators have reported findings indicating highly similar profiles between individuals with FXS and autism versus idiopathic autism and apply categorical or dimensional ratings of autism in FXS [9,16,21-23]. These authors agree with the concept that the autism phenomenon represents a range of behaviors, and perhaps also of other neurologic features [24]. While there is clear consensus regarding the shared phenomenology between FXS and idiopathic autism, there is great debate regarding diagnostic issues. Two of the primary debates on FXS center around questions of whether autism in FXS represents a continuum, with only those most severely affected meeting criteria for autism, and whether autism in FXS is the same as or different from idiopathic autism [9]. Although the literature on the co-morbidity of FXS and autism is extensive, few published studies have longitudinally examined early indicators of autism in infants. Study of the emerging characteristics in FXS is critical for understanding if early features in infants with FXS are associated with later autistic behaviors as reported in idiopathic autism. To date, the studies that have been conducted lend evidence to the fact that indicators of autism are present as early as 12 months of age in males with FXS, and replicate findings in idiopathic autism that implicate difficulties, with disengagement of attention and shifts in behavior at 6 to 12 months of age in the later development of autism [25-27]. Clearly, brain-behavior relationships in idiopathic autism and FXS are complex, and there is currently insufficient evidence to resolve these debates. In summary, however, despite all the controversies generated in the diagnosis of clinical ASD, at present the *FMR1* gene is considered the most common monogenic cause of ASD, and therefore, the molecular diagnosis of FXS should be ruled out in all ASD [28].

Hyperactivity Disorders

Attention deficit and hyperactivity (ADHD) is the most common diagnosable condition in FXS patients, with most males meeting formal criteria at some point in their lives. This condition is typically not stable over time in any given individual [1]. Using DSM-V, several of the ADHD symptoms must be present in individuals prior to the age of 12 years, compared to 7 years as the age of onset in DSM-IV. This change is supported by substantial research published since 1994 that found no clinical differences between children identified at 7 years versus later in terms of the course, severity, outcome, or treatment response. DSM-5 includes no exclusion criteria for people with ASD, since symptoms of both disorders co-occur. The higher inattentiveness, restlessness, fidgetiness and impulsivity in ADHD in children with FXS is suggestive of the ADHD inattentive sub-type compared to ADHD in the general population; these features do not necessarily improve with age [29]. The signature of the FXS is strong unsustained attention, but poor capacity to switch between tasks and weaker inhibitory control [reviewed in 30]. Very young children with FXS are often noted to be physically hypoactive, with somewhat impaired attention. Preschool children can display dramatic increases in activity levels, leading to markedly disruptive behavior. As children grow, hyperactivity declines with increasing body mass, while problems with attention continue throughout life. This can be seen as similar to the course of ADHD in the normal population, though the degree of hyperactivity in FXS is impressive. There is also evidence that the attention deficit seen in males with FXS has a specific profile [31], which is distinct from other causes of developmental disorders, suggesting that the attention problems seen in the course of FXS may represent more than nonspecific immaturity. There is evidence that ADHD symptoms in FXS respond to stimulants [32,33].

Mood Disorders

There has been considerable controversy regarding the behavior phenotype of FXS and the nature of behavioral and emotional problems associated with it.

As described by Backes and colleagues (2000) [34], males with FXS rarely meet formal criteria for a diagnosis of a major mood disorder as defined in DSM-V. Diagnoses such as major depression or bipolar disorder require periods of abnormal mood that are sustained, whereas individuals with FXS typically exhibit labile mood, irritability, self-injurious behavior, and aggressive outbursts of a more fleeting and episodic nature, not meeting the conventional duration criteria. These episodes are typically adaptive, related to environmental stressors and are less frequent in familial or more structured settings. However, affective symptoms can be severe and disruptive, and psychopharmacologic intervention is needed.

Selective serotonin reuptake inhibitors are a commonly employed treatment strategy for affective symptoms, along with other antidepressants, anticonvulsants, and atypical antipsychotics in more severe cases [33]. There have been no clinical trials of any size, open or controlled, of antidepressants or anticonvulsants for the treatment of affective symptoms of FXS. Curiously, the study of valproic acid by Torrioli and collaborators (2010) [35] focused exclusively on ADHD symptoms in boys and they considered that this treatment could be considered as an alternative to treating symptoms with stimulants the efficacy of which needs

to be confirmed by further studies in patients with FXS. Behavioral problems in FXS improve from childhood to young adulthood [36].

Anxiety Disorders

Children with neurodevelopmental disorders, such as FXS, have a higher risk of presenting anxiety. Patients with FXS display a broad range of anxiety symptoms, but these symptoms often do not fit into the established categories of major anxiety disorders employed by the DSM. Cordeiro and coworkers (2011) [37] examined the prevalence of anxiety disorders in a FXS population using DSM-IV-TR criteria. They found that 83% of participants (n=97, ages 5.5–33.3 years) met criteria for any anxiety disorder, and 58% exhibited multiple anxiety disorders. In addition to the high proportion of anxiety disorders in FXS, an important part of individuals with FXS display autistic symptoms as mentioned previously.

Symptoms of anxiety and autism overlap and interrelate within FXS, although these disorders have been distinguished through behavioral and physiological profiles. Kaufmann, Budimirovic and colleagues have published a series of papers characterizing anxiety and autism as distinct social interaction disorders in FXS [38-39]. These authors propose that social anxiety emerges from a combination of lower non-verbal abilities and moderate social withdrawal, whereas autism (either alone or in conjunction with social anxiety) is characterized by a more complex constellation of severe social withdrawal and lower adaptive socialization or verbal skills.

Negative affect is one of the most commonly studied predictors of problem behaviors in non-clinical [40-41] and clinical [42] populations. Negative affect is composed of several specific dimensions of temperament; including fear, approach, soothability, sadness, anger, discomfort, and motor activity [43] and predicts anxiety in preschool boys with FXS [44]. Multilevel models indicate associations between elevated anxiety and higher fear and sadness, lower soothability, and steeper longitudinal increases in approaches in the FXS population.

A minority of males with FXS fulfill formal criteria for the diagnosis of obsessive-compulsive disorder (OCD), while “compulsive symptoms” have been noted in several studies in a large majority of subjects with FXS. In most cases of FXS, individuals exhibit symptoms strongly reminiscent of obsessions and compulsions, but which do not meet the precise psychiatric definitions for these symptoms. Often, pleasure is derived from repetitive and “compulsive” behaviors, in contrast to the ego-dystonic nature of true obsessions and compulsions. Hoarding, counting, and the need for symmetry are all typical symptoms of OCD frequently seen in FXS. Similarly, younger children with FXS meet the criteria for separation anxiety disorder in a small minority of cases [34], while symptoms of separation anxiety, social phobia, panic, and agoraphobia are seen clinically at a much higher rate.

The psychiatric drugs currently available can provide significant symptomatic relief of the hyperactivity, anxiety disorders, and affective disturbances often seen in the course of FXS. However, patients with this syndrome may be especially susceptible to the psychiatric side effects of these medications, requiring particular care in their prescription.

PREMUTATION CARRIERS

For many years, premutation carriers of the *FMR1* gene were considered asymptomatic, but various clinical disorders have been associated in both men and women, being Fragile X tremor–ataxia syndrome (FXTAS) one of the most severe. Individuals with carrier premutation are those that have alleles between 55-200 CGG. Some of the clinical features have been related to the CGG number; in general, more length in the CGG track implies more severe clinical manifestations.

There is a growing body of evidence suggesting that *FMR1* premutation carriers may have increased vulnerability of presenting psychiatric disorders [45]. However, the presence of neuropsychological and behavioral impairment among *FMR1* premutation carriers remains controversial, as these features were initially thought to be associated with the stress of raising children with FXS [reviewed in 46].

Altered neurobehavioral profiles including variation of phenotypes associated with mood and anxiety may be expected among younger premutation carriers.

An increased risk of anxiety and mood disorders among premutation carriers has not been established. Some studies have reported a lack of phenotype [47-48], while others have described repeat length associations with psychiatric symptoms [49-50]. Hessel and coworkers (2005)[51] found that the *FMR1* transcript level, but not repeat length or Fragile X Mental retardation Protein (FMRP) levels, was significantly associated with increased severity of psychiatric symptoms in males, independently of FXTAS status. These results suggest that premutation carriers may be at risk of presenting emotional morbidity; however, phenotypic differences were subtle and of a small CGG effect size.

The largest and most recent study of life-time mood and anxiety in the premutation population was completed by Bourgeois and colleagues (2009) [52]. In this study, the prevalence of anxiety disorders in carriers with and without FXTAS was compared with a very large age-matched national dataset. In terms of all anxiety disorders, only those with FXTAS demonstrated a higher prevalence. Upon separation, this was similarly true for panic disorder, post-traumatic stress disorder and specific phobia. Generalized anxiety disorder and OCD failed to demonstrate any difference between carriers and controls. Only social phobia was found to have higher levels in premutation carriers without FXTAS compared to controls. Chronic anxiety has also been associated with radiological signs on MRI; specifically, the higher the anxiety score the smaller the size of the hippocampus in women with the premutation [53].

Rodriguez-Revenga and collaborators (2008) [54] examined psychiatric and depressive symptoms in 34 *FMR1* premutation carrier mothers of children with FXS in comparison with two control groups (39 mothers with a non-FXS intellectual disability child and 39 mothers from the general population). Both groups of mothers with a child with intellectual disability showed greater susceptibility to psychological problems than the control group without a mentally retarded child, but *FMR1* premutated mothers evidenced a higher tendency to depression. These results suggest that, despite the stress of caring for a child with mental retardation, the premutation by itself could be responsible for some psychiatric traits.

In a screening study of individuals from families with FXS, roughly 14% of boys and 5% of girls with the premutation were found to also have an ASD [10]. Even among those carriers not diagnosed with ASD, related psychological traits are more common among carriers

compared to controls without the premutation. A recent study examined a broad range of pragmatic language skills as well as related behavioral features of the broad autism phenotype among women with the premutation compared with mothers of children with autism, and mothers of typically developing children with no family history of FXS, autism, or language impairment [55]. In this study, conversational samples from a semistructured videotaped interview were used to assess pragmatic language using the Pragmatic Rating Scale (PRS) [56]. This study replicated previous findings in the autism parent group and also showed that women with the premutation exhibited similarly elevated rates of pragmatic language problems relative to the controls. The presence of broad autism phenotype traits was associated with greater expression of autism symptoms in their children with FXS. Other studies have also found increased rates of both social aloofness [49] and a rigid perfectionism [57] among carrier women.

Given its relative rarity in the general population, psychosis has been challenging to study in premutation carriers. Initial linkage analysis failed to show a clear relationship of schizophrenia to the *FMR1* gene [58]. Prevalence studies have found the overall rate of psychotic disorders to be low [49]. There have, however, been several case reports of combined psychotic illnesses and the premutation, including schizoaffective disorder [59] and with combined schizophrenia and schizoid personality disorder [60]. Interestingly, as opposed to frank psychotic disorders, multiple studies have found an increased prevalence of schizotypal personality traits in the carrier population [49,61].

Attention regulation difficulties have been proposed to be a problem in people with the premutation. Notably, when compared with their control siblings, premutation carriers had significantly more issues related to attention than their noncarrier siblings [62]. Inattention and impulsivity amongst *FMR1* carriers can be problematic through adulthood [63], although hyperactivity was not noted to be increased in prevalence.

Dysthymia and bipolar disorder have generally failed to demonstrate significant levels in carriers compared to controls [52].

FRAGILE X ASSOCIATED TREMOR ATAXIA SYNDROME (FXTAS)

FXTAS is an X-linked neurodegenerative disorder affecting up to 45.5% of males and 16.5% of females carrying a premutation in the *FMR1* gene [64-65].

There is a growing body of literature suggesting that the neuropsychiatric features of FXTAS follow a fronto-subcortical pattern with primary impairments in executive function and increased vulnerability to mood and anxiety disorders [51,53, 66-69]

Increased rates of psychiatric symptoms may represent early markers of neurodegenerative diseases such as Parkinsons Disease (PD) [70] and Huntington's Disease [71], which have also been reported among *FMR1* premutation carriers without FXTAS, including obsessive-compulsive symptoms [51], social phobia [72], depression [50], schizotypal features [73] and abnormalities in social cognition [74].

Three studies have examined the psychiatric features of FXTAS: (1) Bacalman et al. (2006) [67]; (2) Adams et al. (2010) [53]; and (3) Hashimoto et al. (2011) [69]. They showed no significant association between FXTAS and different psychiatric diagnoses. The studies compared the prevalence of neuropsychiatric symptoms between individuals with FXTAS and

matched controls with normal *FMR1* alleles (cohort 1 and 3), and between asymptomatic *FMR1* premutation carriers in cohort 2.

Symptoms of depression were significantly elevated among males with FXTAS when measured using the informant-rated NPI in cohort 1; however, self-reported symptoms measured using the SCL-90-R in cohort 3 were comparable to controls. Women with FXTAS (cohort 2) tended to report higher rates of depression than controls with normal *FMR1* alleles; however, this difference did not withstand correction for multiple comparisons.

Anxiety was significantly elevated among older males with FXTAS compared to controls in cohort 2; however, in cohort 1 the group difference (50% FXTAS group vs. 0% control group) was not significant, possibly due to the small sample size ($n=14$). Male carriers with FXTAS exhibited elevated rates of anxiety in cohort 3 (Cohen's $d=0.69$) and comparable scores in cohort 2. Females with FXTAS (cohort 2) exhibited higher rates of anxiety and obsessive-compulsive symptoms compared to controls with normal *FMR1* alleles and asymptomatic *FMR1* premutation carriers.

Males with FXTAS (cohorts 2 and 3) reported significantly higher rates of obsessive compulsive symptoms compared to asymptomatic carriers (Cohen's $d=0.92$, cohort 7), but not controls (cohort 2). Symptoms of anxiety among asymptomatic male and female *FMR1* premutation carriers were compared to controls with normal alleles in cohort 2 and no group differences were detected.

Additional informant-rated behavioral disturbances found to be significantly elevated among males with FXTAS (cohort 1) compared to controls included apathy, irritability, disinhibition, and agitation/aggression (Cohen's $d=3.53$) [67].

Increased obsessive-compulsive and depressive symptoms (but not anxiety) were also associated with decreased left amygdala volume among males with FXTAS in cohort 3 (all $ps<0.02$) [69].

It is difficult to determine the psychiatric features most commonly associated with FXTAS based on this limited number of studies; however, the evidence available suggests that FXTAS may be associated with increased rates of depression, anxiety and obsessive-compulsive symptoms. This is supported by a previous systematic review that included case reports and case series, suggesting elevated rates of mood and anxiety disorders among those with FXTAS [52].

Emerging evidence suggests that a subset of carriers without FXTAS may exhibit cognitive deficits, psychiatric symptoms, and changes in brain structure and function which may be modulated by *FMR1* gene expansion [51,53,69,74-75]. Specifically, abnormalities in structural and functional connectivity have been described in the middle cerebellar peduncles, hippocampus, amygdala and prefrontal cortex, raising the possibility that these early indicators of fronto-subcortical and cortico-cerebellar dysfunction may be detectable prior to the onset of clinical symptoms. The capacity to identify the subjects most at-risk or closest to onset of illness would be invaluable for recruitment into clinical trials as treatments for FXTAS become available. In the absence of longitudinal follow-up of these cohorts, however, it is unclear whether cognitive, psychiatric and radiological changes observed in some asymptomatic carriers represent an independent developmental phenotype associated with the *FMR1* premutation, or serve as early indicators of later progression to FXTAS.

Intermediate *FMR1* alleles (alleles within the 45–54 CGG repeat range are described as an ‘intermediate or gray zone’). During the last few years, several studies have reported an excess of intermediate *FMR1* alleles in patients with cognitive and/or behavioral phenotypes [76-80]

while other studies do not support this relationship. Madrigal and colleagues (2011) [81] did not find evidence of an association between intermediate alleles and behavioral or cognitive phenotypes, suggesting that intermediate alleles are not clearly implicated in these pathologies.

A frequent concern in FXS screening is the genetic counseling to intermediate allele carriers. Currently, the follow-up of individuals with no AGG interruptions is indicated, despite the low risk of expansion in the next generation. Intermediate alleles should not be considered a risk factor for ID or behavioral phenotypes. Nonetheless, these alleles should be characterized to provide accurate genetic counseling [81].

Table 1. Percentage of affected individuals for the psychiatric aspects

Psychiatric features	FXS	PM with FXTAS	PM without FXTAS	References
Autism traits	>90%			[14]
Autism criteria DSM-IV	30-50%			[11-13]
Autism spectrum disorders	60-74%		14% Males 5% females	[11-12,57]
ADHD	30% Females 60% Males		30% Females 14% Males	[62]
Affective disorders	22% Females 12% Males	65%	55.7% 34.2%	[49,62,72]
Anxiety	83%	52%	35-40%	[37,49,72,]

CONCLUSION

FMR1 is the first monogenic cause of autism disorder. Approximately 30–50% of FXS meet full DSM-IV-TR criteria for autism, 60–74% fulfilling criteria for an ASD and over 90% of individuals display some form of atypical behavior characteristic of autism. Molecular diagnosis of FXS should be ruled out in all ASD. Increased rates of psychiatric symptoms may represent early markers of neurodegenerative diseases which have been reported among *FMR1* premutation carriers with and without FXTAS; including obsessive-compulsive symptoms, social phobia, depression, schizotypal features, and abnormalities in social cognition. Altered neurobehavioral profiles including a variation of phenotypes associated with mood and anxiety may be expected among younger premutation carriers. The trend is to present higher rates of anxiety and mood disorders in premutation carriers, but no study has found significant differences between carriers and the control population.

ABSTRACT

The expansion of the CGG trinucleotide located within the 5'UTR of the *FMR1* gene is involved in a growing number of diseases; the most well-established are Fragile X Syndrome (FXS), Fragile X Tremor/Ataxia Syndrome (FXTAS) and Fragile X Primary Ovarian Insufficiency (FXPOI). Whereas full mutation alleles (>200CGGs) are responsible for the FXS, smaller expansions called premutation alleles (55-200CGGs) are associated with FXTAS and FXPOI. Numerous evidence have currently been reported suggesting that premutation alleles give rise to an increased risk for carriers of these alleles in relation to additional medical, psychiatric and cognitive features which occur at a greater frequency than what would be expected for the general population. In this chapter, we review the clinical features including peripheral neuropathy, immune-mediated disorders, migraines and neurocognitive involvement which have been suggested to be associated with premutation alleles. In addition, the current understanding of the pathogenic molecular mechanisms that give rise to the spectrum of *FMR1* premutation associated disorders is also reviewed. Although further research is needed in order to shed light on the factors underlying the common incomplete penetrance applicable to all phenotypes associated with the premutation, it is likely that a combination of environmental and genetic factors with differences in intrinsic susceptibility may modulate the appearance and the severity of these disorders.

Keywords: *FMR1* premutation, fibromyalgia, thyroid disease, peripheral neuropathy

INTRODUCTION

In the last years, there has been intense interest in identifying and characterizing the Fragile X premutation-associated phenotypes from the perspective not only of basic science but also of public health given its high prevalence affecting 1:250 females and 1:800 males among the general population [1]. Historically, carriers of *FMR1* premutation (PM) alleles were considered to be clinically unaffected, since the gene is generally not methylated and these individuals do not present intellectual disabilities (ID). The significance of these alleles was generally thought to be their propensity for expansion to the full mutation range (>200 CGG repeats) during maternal transmission resulting in transcriptional silencing of *FMR1* gene, absence of the encoding fragile X mental retardation 1 protein (FMRP) and manifestation of fragile X syndrome (FXS) [2,3]. Although, the features of this expansion are not fully understood, it is currently accepted that they depend on the size of the maternal allele and also on the number of the AGG interruptions within the CGG-repeat track [4]. The AGG interruptions are likely to have stabilizing effects during transmission by decreasing the risk of DNA polymerase slippage during DNA replication [5]. In PM male carriers there is a relative stable transmission, and thus, the risk of expansion to a full mutation is negligible [reviewed in 6].

Despite the belief that PM carriers do not present signs of clinical involvement, prior to the discovery of the gene *FMR1* Cronister and collaborators (1991) [7] reported, higher rates of premature ovarian failure (POF) among women heterozygous for X-chromosome fragility. Later, Allingham-Hawkins and colleagues (1999) [8] established PM alleles as a significant risk factor for POF based on the study of 760 women in which 16% of PM carriers were affected with POF whereas none of the full mutation carriers and just one (0.4%) of the controls presented with POF [8]. Currently, the association between ovarian deficiency and PM female carriers, namely Fragile X-Primary ovarian Insufficiency (FXPOI), is well-established, presenting an incidence of around 20% in these women and estimated at around 1% among the general population. Chapter 2 describes the features of FXPOI. Ten years after, the first description of a neurodegenerative disorder named Fragile X Tremor Ataxia Syndrome (FXTAS) associated to older adults PM carriers was made by Hagerman and colleagues (2001) [9]. This syndrome is characterized by white matter changes and global brain atrophy, presenting with core features of intention tremor and gait ataxia. Details of FXTAS are described in Chapter 3.

Over the past 10-15 years, an increasingly broad spectrum of clinical manifestations has been related to individuals who are carriers of PM alleles (Table 1). Domains of clinical involvement seen in some, but not all carriers of PM encompass the presence of medical, emotional and cognitive manifestations which have been widely reported to occur more frequently among PM carriers than in the general population. Some of these features have recently been classified as being ‘definitely related’, ‘probably related’, ‘possibly related’ or ‘not likely related’ to the molecular changes associated with an *FMR1* expansion based on clinical and previously reported data [reviewed in 10].

Coffey and collaborators (2008) [11] reported the first evidence of an expanded clinical phenotype of women with the PM. In this study, PM female carriers without core features of FXTAS showed significantly more complaints of chronic muscle pain, persistent paraesthesias in the extremities, and a history of tremor than controls. Furthermore, a significantly greater

presence of medical co-morbidity was detected in females with definite or probable FXTAS, with an increased prevalence of thyroid disease, hypertension, seizures, peripheral neuropathy, fibromyalgia compared with controls [11]. In addition, some of the comorbidities associated with FXTAS beyond central nervous system involvement, specifically peripheral neuropathy [11,12] and neuroendocrine dysfunction [11,13-15] have also been associated with PM carriers without FXTAS. Moreover, there is increasing evidence that young PM carriers present increased rates of neurodevelopmental phenotypes such as attention-deficit hyperactivity disorder (ADHD), autism spectrum disorder (ASD) and seizures [reviewed in 16]. Furthermore, increased rates of psychiatric involvement, particularly depression and anxiety have also been associated with FXTAS among adult PM carriers [reviewed in 17]. Neuropsychiatric aspects are discussed in Chapter 4.

CLINICAL FEATURES ASSOCIATED WITH *FMR1* PREMUTATION CARRIERS

Neuropathy

Peripheral neuropathy is characterized by a damaging of peripheral nerves which carry information to and from the brain as well as to and from the spinal cord to the rest of the body.

Depending on the type of nerve affected it may promote impaired sensation, movement, gland or organ function. The association between neuropathy and *FMR1* alleles was first reported in PM carriers with FXTAS [9,18]. Thereafter, Berry-Kravis and collaborators (2007) [12] reported the first evidence that signs of neuropathy on clinical examination are associated with PM carrier status based on neurological examination data from 207 unrelated individuals. Results from this study revealed that the degree of clinical involvement strongly correlated with the CGG repeat length in males since these individuals presented significantly higher mean scores in the neuropathy screening scale score ($P=0.0014$), the vibration score ($P=0.0015$), and the reflex score ($P=0.0014$) than sex-matched controls suggesting that PM male carriers present higher impairment of both distal vibratory sense and reflexes [12]. The lack of significant differences among PM female carriers presumably reflects the broad variation in clinical involvement among carriers as a result of variation in the X-chromosome activation ratio as well as the decreased penetrance of the clinical manifestation due to the protective effect of the second non-mutated X chromosome [12]. Afterwards, Coffey and collaborators (2008) [11] demonstrated that females with PM alleles also presented significantly higher signs of neuropathy based on findings from 128 PM female carriers without FXTAS. In this study it was shown that these women presented a significant rate of numbness and tingling and muscle pain in the extremities, albeit evidence of neuropathy is increased in PM female carriers presenting with FXTAS [11]. It has been suggested that neuropathic symptoms in PM female carriers are manifested together with the emergence of FXTAS disease [reviewed in 10].

Immune-Mediated Disorders

Numerous reports support elevated rates of immune-mediated disorders (IMD) in PM female carriers, particularly regarding hypothyroidism and fibromyalgia [11, 13-15]. In contrast, IMDs have not been evidenced among males with the premutation, likely due to the relative rarity of these disorders among the general male population. In a recent study, Winarni and colleagues (2012) [15] examined the relative likelihood of large clinical manifestations among 344 female carriers of PM alleles and 72 controls including autoimmune thyroid disorder, multiple sclerosis, Sjögren syndrome, rheumatoid arthritis, systemic lupus erythematosus, Raynaud's phenomenon, irritable bowel syndrome and optic neuritis. The results of this study evidenced that among women over 40 years of age 46.54% of PM females without FXTAS experienced one or more of the IMDs surveyed, and the prevalence increased to about 72.73% for those with FXTAS compared to 31.58% for the control group [15]. With respect to FXPOI, both groups of PM females carriers present higher odds ratios of IMDs compared to controls, and similarly, when considering FXTAS symptoms, the odds ratio of IMDs among PM female carriers presenting with FXPOI is about 2.4-fold higher when compared to those without FXPOI. Moreover, these authors found that an autoimmune thyroid disorder was the most common IMD followed by fibromyalgia and irritable bowel syndrome [15].

Increased penetrance for both thyroid disease and fibromyalgia has been broadly reported among PM female carriers [13], although the penetrance of these disorders is highly variable among the general population since it increases with age. For thyroid disease, it has been suggested that the association with PM alleles may be more relevant in older women [10] due to the lack of statistical significance when considering women between 18 and 50 years of age

[19]. Nonetheless, in the general population the penetrance estimated for thyroid disorders is of around 10% [20] and around 2-4% for fibromyalgia whereas it has been estimated to be around 15.9% and 24.4%, respectively, among PM female carriers [13]. Conversely, in 700 unrelated Spanish patients with fibromyalgia the frequency of PM alleles did not significantly differ from the estimated rate in the general population [21]. In contrast, another study found a higher incidence of PM alleles among a Spanish female fibromyalgia cohort. Indeed, the incidence of PM alleles was 1 of 88, being 1 of 250 in females in the general population [22]. These controversial results are likely to be caused by a sample size effect since the data reported by Martorell and colleagues (2012) [22] were based on the screening of 353 females whereas the data presented by Rodriguez-Revenga and coworkers (2013) [21] were based on 700 samples. Nonetheless, it has been shown that the pathophysiology of fibromyalgia involves hyperexcitability of central neurons through several synaptic and neurotransmitter/neurochemical mechanisms [reviewed in 23] suggesting that it could arise through an alteration of pain neurotransmitter mechanisms among PM female carriers [14].

Finally, it has been recently demonstrated that individual carriers of PM alleles present an immune dysregulation and decreased immune responses when compared with healthy controls [24]. Moreover, it has been found that PM carriers present a reduction in the levels of cytokine production which is negatively associated with CGG repeat length, mainly with IL-12 production [24]. Furthermore, these women have also been shown to present a decrease in the relative levels of the surface marker CD25 in T cells suggesting potential differences in the activation of T-cells that regulate immune response [24].

Migraines

Au and collaborators (2013) [25] have recently reported that PM carriers show increased rates in the prevalence of migraines based on physical and medical examination of 315 PM carriers (203 females and 112 males) and 154 controls (83 females and 71 males). Migraine is a neurologic disorder characterized by light and sound sensitivity and pulsatile pain, which is thought to have a polygenic and multifactorial etiology. The prevalence of migraine among the general population is estimated around 27.3% in women and 9.7% in men [26], reaching up to 54.2% and 26.79% among female and male PM carriers, respectively, both resulting in statistical significant differences [25]. In addition, this significance was obtained considering both those affected with and also those without FXTAS, adjusted for age. However, the risk of migraine headaches was not correlated with either CGG repeats or *FMR1* mRNA expression [25].

Neurocognitive Features

The expanded range of clinical involvement associated with PM carriers also includes an alteration of various cognitive domains including executive function, working memory and arithmetic skills which become apparent even in young individuals, with a usually more progressive course in PM individuals than in the general population [reviewed in 10]. However, neurocognitive deficits are reportedly more frequent in male than in female carriers of PM alleles. Results reported by Kogan and collaborators (2008) [27] revealed that the CGG

expansion confers a significant risk for working memory difficulties based on a controlled study of 40 PM male carriers without manifest symptoms of FXTAS. In addition, Cornish and colleagues (2009) [28] reported neuropsychological measures in PM males regarding core subcomponents of working memory such as verbal memory, visual-spatial memory, and central executive memory revealing that PM males present specific vulnerability in executive control of memory including tasks requiring simultaneous manipulation and storage of new information, regardless of the presence of FXTAS symptoms. These authors revealed an impairment of the central executive working memory among PM male carriers without FXTAS, which was significantly correlated with larger CGG repeat expansions, whereas FXTAS patients demonstrated a more general impairment in terms of phonological working memory in addition to central executive working memory [28]. Moreover, language dysfluencies associated with deficits in organization and planning have been evidenced among PM female carriers [29]. Past research has demonstrated that language dysfluencies are an indicator of executive functioning deficits which are characteristic of other neurodegenerative disorders such as Parkinson and Alzheimer diseases.

Regarding arithmetic skills it has been suggested that PM female carriers show weaknesses in mathematical tasks [30] and this has recently been supported by other groups [31]. Furthermore, it has been demonstrated that PM carriers from 19 to 45 years of age show impairment in spatiotemporal processing which may underlie the impairments observed in arithmetic skills among these individuals since the representations of space and time provide the foundation for an understanding of numbers [32].

Although further research is needed, it has been suggested that determining whether cognitive impairments are detectable in PM carriers without FXTAS should be prudent since it may not only be an early indicator of cognitive decline in PM carriers [29] but could also be used as a biomarker of disease progression if these features precede motor impairment [32].

CURRENT UNDERSTANDING OF THE MOLECULAR MECHANISMS UNDERLYING PREMUTATION-ASSOCIATED PATHOLOGIES

Premutation-associated phenotypes have been mainly attributed to a pathogenic mechanism involving a gain-of-function toxicity of the expanded *FMR1* mRNA, a process entirely distinct from the FMRP deficiency responsible for the FXS phenotype [reviewed in 33]. This observation was based on the restriction of these clinical phenotypes to the premutation range in which the molecular signature is a 2-8 fold increase in the expression of the PM mRNA and, paradoxically, a slight reduction in Fragile X Mental Retardation Protein (FMRP) levels [34]. The mechanisms underlying the increased transcriptional activity of the PM alleles remain unclear, however, it has been reported that these alleles use differential transcriptional start sites leading to different expression compared to non-expanded *FMR1* alleles [35]. On other hand, it has also been suggested that the reduction of FMRP in PM carriers may promote an added contribution to the clinical involvement observed in both children and adults related to phenotypes associated with reduced cognition and disturbed behavior [36]. However, the FMRP deficiency cannot be a driving factor in the PM-associated disorders since FXTAS and FXPOI are not experienced by full mutation carriers. Despite wide reports that the levels of FMRP expression are only slightly decreased in patients with FXTAS, most of these

measurements have been performed using lymphocytes or whole blood samples rather than brain tissue, in which changes are likely to be more robust [reviewed in 37]. The efficiency of FMRP translation is associated with the length of the CGG expansion in light of impairment in translation of larger CGG tracks by interference with ribosomal scanning through the 5'UTR, thereby preventing appropriate loading of the expanded *FMR1* mRNA into polyribosomal complexes [38-40].

It is currently considered that the dual mechanism of involvement, the excess of PM mRNA expression and the decrease in FMRP translation, is a double hit which may promote phenotypic features of FXS and PM associated disorders [reviewed in 33, 41]. Notwithstanding, the reduction of FMRP synthesis, the phenotype of PM carriers, is different from carriers of full mutation alleles since milder protein deficiency among PM carriers usually leads to mild developmental problems with these individuals having higher IQs and less severe behavioral problems than those with FXS [reviewed in 42]. A FMRP deficit has been correlated with lowered activity of the amygdala among PM male carriers compared to controls on functional magnetic resonance imaging whereas increased levels of expanded mRNA have been strongly associated with obsessive-compulsive symptoms and psychoticism in PM male carriers [43,44]. It has also been described that RNA toxicity leads to the up-regulation of the heat shock proteins Hsp70 and α B-crystallin, which may stimulate immune dysregulation [15]. Regarding migraines, their association with mitochondrial dysfunction is well established. Interestingly, there is evidence pointing to a deregulation of mitochondrial function among PM carriers [45-47], therefore the increased prevalence of migraines in PM carriers may be the result of RNA toxicity leading to mitochondrial deregulation [25]. Likewise, RNA toxicity has also been proposed to shed light on the high rate of thyroid dysfunction among females with the PM by causing a direct effect on the hypothalamic-pituitary-adrenal axis or on the thyroid gland. Additionally, RNA toxicity has also been proposed to promote an autoimmune mechanism or apoptosis in thyroid cells [11]. However, data reported by Cunningham and coworkers (2011) [48] show that the presence of PM alleles promotes migration defects in the neocortex and altered expression of neuronal lineage markers among embryonic PM mice. These results support the hypothesis that the role of the RNA toxicity may be restricted to the initial triggering events since many features of the neuronal and astrocytic cellular phenotype observed in FXTAS patients are already present in the neonatal period, suggesting that the clinical involvement among children carriers of PM alleles may be manifestations of this early, non-degenerative process [reviewed in 33].

The sequestration hypothesis of RNA toxicity was first proposed and established for myotonic dystrophy type 1 caused by an expansion of a CTG repeat in the 3'UTR of *DMPK* gene [reviewed in 49]. Particularly, in Fragile X PM the model hypothesized that expanded CGG repeats form hairpin loops which are sticky and recruit an excess of specific RNA-binding proteins, resulting in a functional insufficiency of the sequestered proteins and leading to cell dysfunction and death [50]. Although the initial triggering events in these disorders are based on RNA toxicity, this model does not provide evidence regarding cell sickening and death. In this way, there are several candidate downstream pathways, although alterations of both mitochondrial function and calcium regulation are emerging as core mediators of cellular deregulation and dysfunction [reviewed in 31, 39]. The increased expression of the expanded *FMR1* mRNA is thought to be the main cause of clinical involvement in PM carriers since the *FMR1* mRNA and the sequestered proteins form aggregates leading to intranuclear inclusions present in several tissues. Interestingly, the expanded mRNA of *FMR1* is detected within the

inclusion whereas FMRP is not present [51]. Furthermore, proteomic analysis of these inclusions revealed a large number of proteins presented in the aggregates, including the RNA binding protein hnRNP A2/B1, the nuclear envelope protein lamin A/C, the small heat shock protein α B-crystallin [52], the splicing factor Sam68 [53] and part of the microRNA processor complex DGCR8 [50]. Indeed, it has recently been demonstrated that the sequestration of DGCR8 promotes the deregulation of microRNAs biogenesis, suggesting a central role of DGCR8 as an inductor of RNA toxicity by leading to cell dysfunction and cell loss [50].

Intranuclear inclusions, which represent the neuropathological hallmark of FXTAS [52], have been also detected among PM carriers through different cell types including the central and peripheral nervous system and other tissue including the adrenal glands, the testes, pancreas and heart [54-58]. Recently, Hunsaker and colleagues (2011) [58] reported autopsy findings from ten PM carriers with FXTAS in which intranuclear inclusions were detected throughout multiple tissues including the hypothalamic-pituitary-adrenal axis, pineal gland, cardiac conduction system, peripheral nerves and autonomic ganglia, the thyroid gland, the digestive system, the testes and pancreas. The broad distribution of these inclusions suggests that many organ systems may be affected by RNA toxicity. Nevertheless, it is necessary to study the processes underlying inclusion formation in depth to address whether they themselves are toxic or reflect cellular dysfunction [58].

Furthermore, additional mechanisms have been proposed as possible triggering events in the PM-associated disorders, although most evidence support CGG-repeat mediated protein sequestration [reviewed in 33,37]. These mechanisms include a RNA-mediated protein aggregation model whereby the CGGs contained within the *FMR1* mRNA might promote a conformational transition in proteins with prion-like domains that may initiate a cascade of protein aggregation similar to what occurs in amyloid plaque formation in Alzheimer's disease. Moreover, the production of a toxic polyglycine peptide has also been proposed as an alternative toxicity model by a non-AUG-initiated (RAN) translation [59]. In addition, a specific splicing isoform is detected exclusively with transcripts of PM alleles suggesting a possible role of antisense transcripts generated at the *FMR1* locus [60].

Otherwise very little attention has been focused on the other end of the spectrum, the so-called "low-normal" numbers of CGG repeats, up to 23 trinucleotide repeats. In this framework, data based on genotype-phenotype correlations have recently been reported suggesting that this range of CGG repeats may have substantial implications for cognitive functioning, cancer, and the odds of having children with neurodevelopmental or neuropsychiatric conditions [61]. Despite these range of CGG number not being associated with altered FMRP synthesis, Chen and co-workers (2003) [62] reported that the efficiency of FMRP translation was based on the number of CGG repeats, conferring the greatest efficiency of protein synthesis to the allele of 30 repeats. Thus, inefficient translation may be related to the clinical manifestations associated with the low numbers of CGG repeats. Likewise, Ramocki and Zoghbi (2008) [63] suggested that imbalances in homeostatic controls of multiple genes including *FMR1* may partially promote the appearance of neurodevelopmental and neuropsychiatric disorders.

At this point, the difficulty in understanding PM-associated pathologies lies in the inability of prediction of which PM carriers will develop any of these phenotypes. The incomplete penetrance across the phenotypic spectrum is likely to be associated with a combination of genetic and environmental factors which may confer specific vulnerability to PM carriers (Figure 1).

Figure 1. Diagram of the potential players contributing to the clinical involvement associated to PM carriers.

Genetic factors that may contribute to the PM-associated disorders include CGG repeat length, expression levels of the expanded *FMR1* mRNA, aberrant translation of the repeat sequence as well as genomic changes in other regions of the genome. Within this framework, specific polymorphisms of the *CRHR1* gene have been associated with female clinical involvement (rs7209436), particularly with depression and anxiety mainly as this gene regulates the expression and release of ACTH from the anterior pituitary gland which, in turn, stimulates the release of cortisol from the adrenal cortex [64]. Furthermore, risk factors for other neurodegenerative disorders such as allele $\epsilon 4$ of the *APOE* gene may also influence the risk of FXTAS as a higher frequency of these alleles has been reported in PM carriers with compared to those without FXTAS [65]. Moreover, it has recently been suggested that

individuals who are carriers of PM alleles presenting with ID, seizures or ASD are likely to have a second hit since PM carriers show a significant enrichment ($P=2.27\text{e-}07$) of CNVs compared to controls [66]. Furthermore, these authors found an association between the presence of rare CNVs (not detected in 8000 controls) among PM carriers with either autistic traits or neurological involvement, suggesting that they may have a possible role in this phenotypic variability [66]. Regarding environmental factors, it has been suggested that smoking, prolonged surgery with anesthesia, drug and alcohol abuse or the stress of carrying a child with FXS are also puzzling factors which may act as additional determinants for the phenotypic variability among PM individuals [reviewed in 41,42]. Finally, further longitudinal studies are required to determine the context in which any of the PM-associated phenotypes are developed and what protective factors might reduce the risks of more negative outcomes [reviewed in 10].

CONCLUSION

Overall, it is currently accepted that PM alleles led to multiple distinct clinical features which are present at a greater frequency among PM carriers than what would be expected in the general population. However, the association of the PM with the phenotypes reviewed in this chapter is less well established than its association with FXTAS and FXPOI. Although further research is needed in order to shed light on the factors underlying the common incomplete penetrance applicable to all phenotypes associated with the PM, a combination of environmental and genetic factors with differences in intrinsic susceptibility likely modulate the appearance and the severity of these disorders.

ABSTRACT

Fragile X syndrome is the most common form of inherited intellectual disability, with an estimated incidence of 1 in 4,000 males and 1 in 6,000 females. Each diagnosis of an *FMR1* mutation has far reaching clinical and reproductive implications for the extended family. Until now genetic counseling was offered based on the expansion risk in premutation carrier women, but the description of *FMR1*-associated disorders has increased the complexity of the genetic counseling for FXS families, especially *FMR1* premutation carriers. Male individuals carrying full mutated alleles present with intellectual disability while the penetrance is incomplete in females (30-50%). Premutation allele carriers are intellectually unaffected, but several *FMR1* premutation-related disorders have been described. The most prevalent are fragile X-associated primary ovarian insufficiency and fragile X-associated tremor/ataxia syndrome, but behavioral features such as impaired executive function, social deficits or anxiety have also been related to several *FMR1* premutation carriers. Premutation women have 50% of risk of transmitting a premutation/full mutation allele to their offspring, depending on the CGG expansion repeat and the presence of AGG interruptions. On the contrary, premutation men carriers will only transmit the premutation allele to their daughters. Some issues such as risk assessment for intermediate alleles and the clinical prognosis for females with full mutations still remain challenging. Genetic counselors must have an updated and solid understanding of this genetic condition and the *FMR1*-associated disorders in order to cover all the counseling aspects of these disorders.

Keywords: *FMR1*, FXS, premutation alleles, full mutation alleles, genetic counseling, intermediate alleles

INTRODUCTION

The World Health Organization defines Genetic Counseling as the process through which trained genetic counselors inform about the genetic aspects of a particular genetic disease to those who are at an increased risk of developing the disorder or of passing it on to their unborn offspring. A genetic counselor must provide accurate information to the patient and their families about the clinical consequences of the conditions, the inheritance of illnesses and their risks of recurrence, management and/or treatment, quality of life, life expectancy and social aspects. These professionals must then work in a wide variety of fields such as general genetics, prenatal care or family planning. The counseling process consists of two stages: pre and the post-test genetic counseling. In pre-test genetic counseling individuals are informed about the purpose of the test, the clinical consequences of the conditions, including the phenotypic features, inheritance patterns, the reliability and limitations of the test and the possible psychological impacts to the counselees and their relatives.

In post-test genetic counseling, after disclosure of the test results, the counselor should focus on the emotional impact on the counselee and the relatives involved. The counselees must be informed about implications to them and their close relatives, including management and/or treatment options, quality of life, life expectancy and available reproductive choices. Counselors must ensure the privacy and confidentiality of the results.

GENETIC COUNSELING IN *FMR1*-ASSOCIATED DISORDERS

Fragile X syndrome (FXS, #300624) is the most common form of inherited intellectual disability (ID), with an estimated incidence of 1 in 4,000 males and 1 in 6,000 females [1]. The molecular basis of this syndrome is mainly the expansion of an unstable CGG repeat in the 5' untranslated region of the fragile X syndrome gene (*FMR1*). The polymorphic CGG repeat of the *FMR1* gene is distributed in the population in four allelic classes according to repeat length (Table 1). Alleles ranging from 6 to 44 CGG repeats are the most common in the general population and have a stable transmission to the next generation. Alleles within the 45–54 CGG repeat range are called intermediate alleles and most are stable. Individuals carrying intermediate alleles are phenotypically normal. Alleles about 55–200 repeats are called premutation alleles. These alleles are associated with a significant elevation of *FMR1* mRNA levels [2-3] and are highly unstable during maternal transmission. Premutation carrier individuals do not present with ID, but they have a risk of developing fragile X-associated tremor/ataxia syndrome (FXTAS), premature ovarian insufficiency (FXPOI) or other psychological symptoms [4-7]. Finally, expansion of the repeat region to more than 200 CGG trinucleotide sequences is called full mutation. *FMR1* is an X-linked gene regulated by methylation of the promoter during X inactivation in somatic cells of females. This leads to gene silencing and insufficient synthesis of the *FMR1* protein (FMRP). Expansions over 200 CGGs lead to hypermethylation of the CpG island resulting in non-expression of the *FMR1* gene and absence of the FMRP. The lack of FMRP is the direct cause of the FXS phenotype [8]. Besides CGG repeat expansions, it has been reported that almost 1% of individuals with FXS have a partial or full deletion, or point mutation of the *FMR1* gene [9-12].

Until now genetic counseling was offered based on the expansion risk in premutation carrier women, but the description of *FMR1*-associated disorders has increased the complexity of the genetic counseling for FXS families, particularly to *FMR1* premutation carriers. Furthermore, some issues such as risk assessment for intermediate alleles and the clinical prognosis for females with full mutations still remain challenging.

Most of the families who first receive a diagnosis of FXS have no prior knowledge of *FMR1*-premutation disorders, and it is essential that individuals under study receive pre and post genetic counseling, including information about possible outcomes and the implications of carrying full, premutation or intermediate alleles. Genetic counseling of FXS requires attention to a wide range of clinical manifestations including developmental, neurodegenerative, and reproductive symptoms that may vary in age of onset and severity. Counselors must have a solid understanding of this genetic condition, including the trinucleotide repeat instability and the phenotypic variability. Table 1 shows associated *FMR1* allele phenotypes.

Table 1. *FMR1* alleles and associated phenotypes

Allele	CGG repeat range	Phenotype
Normal	5-44	Normal
Intermediate	45-54	Normal
Premutation	55–200	Normal, FXTAS, FXPOI and others
Full Mutation	>200 (methylated)	ID in 100% males and reduced penetrance in females (30-50%)

ASSESSMENT RISK BASED ON CGGs EXPANSION

Normal Range and Intermediate Alleles

Alleles ranging from 6 to 44 CGG repeats, the most common in the general population, and most of the intermediate alleles have stable transmission to the next generation. Intermediate alleles may show some instability, including expansion to a full mutation in two generations [13-15].

Premutation Alleles

Premutation alleles are highly unstable during maternal transmission and may expand to a higher CGG repeat size or even to a full mutation in only one generation. Even expansion of paternal premutation alleles is possible; the expansion from a premutation allele to a full mutation has only been observed through female meioses. Thus, all the daughters from a premutation male will inherit the premutation allele and will not manifest FXS. Table 2 shows the risk of expansion of the different allele types. The expansion risk of a *FMR1* allele depends both on CGG repeat size and the presence of AGG interruptions. In 1994, Eichler *et al.* suggested that AGGs interspersed within the *FMR1* repeat region may be linked to repeat stability and the risk of expansion [16]. In the general population, almost 95% of alleles have

one or two AGG interruptions, which the most common allele pattern is two AGGs at positions 10 or 11 and 20 or 21 repeats. In contrast, alleles in FXS families contain no or few AGGs at the 5' end and they contain long stretches of uninterrupted CGGs at the 3' end [16,17]. Presumably maternal alleles with no AGG interruptions confer increased risk for unstable transmissions and thus, the inclusion of AGG genotype studies would be of benefit in clinical practice. AGG testing is expected to reassure premutation carriers with AGG interruptions while alerting premutation carriers with alleles without AGG interruptions who would have the highest risk for instability.

Table 2. Risk of expansion of *FMR1* alleles

Allele	CGG repeat range	Risk of expansion to a full mutation for females*
Normal	5-44	0%
Intermediate	45-54	0%
Premutation	55-59	3.70%
	60-69	5.30%
	70-79	31.10%
	80-89	57.80%
	90-99	80.10%
	>100	94-100%
Full Mutation	>200 (methylated)	

*[68-70].

Full Mutation Alleles

Full mutated males never transmit the full mutated allele to their daughters, only an allele in the premutation range. Full mutated females have a 50% of transmission risk of the full mutated allele to their offspring; all male descendants carrying the full mutation allele will be affected while a smaller percentage of women will present the syndrome.

GENETIC COUNSELING BASED ON *FMR1* ALLELES

Intermediate Alleles

Intermediate alleles present a 45–54 CGG repeat range [18] and have a frequency in the general population of 1/35 to 1/57 females [19,20]. Intermediate allele carriers do not manifest ID, FXTAS or FXPOI, although some groups have suggested associations between intermediate alleles and some disorders such as Parkinson's disease [21], primary ovarian insufficiency [22], and autism and cognitive disabilities [23,24]. However, these findings have not consistently been supported by other studies [25-27]. A frequent concern in FXS screening is the genetic counseling to intermediate allele carriers. Currently, the follow-up of individuals with no AGG interruptions is indicated, despite the low risk of expansion in the next generation.

Premutation Alleles

Individuals carrying premutation alleles are intellectually unaffected, but in the last decades several premutation-related disorders have been described. Among them the most prevalent are FXPOI and FXTAS [28,29]. In addition, behavioral features such as impaired executive function, social deficits or anxiety have been related to some *FMR1* premutation carriers [30]. Premutation alleles contain trinucleotide expansions in the range of 55 to 200 CGG repeats. In Western populations premutation frequencies in females range from 1/151 to 1/259, but there is some evidence of ethnic and racial variability. In Israel, for example, the premutation frequency is around 1/113 and in Taiwan 1/837 [20,31-33]. Some authors state that the different reproductive aptitudes of female premutation carriers and the differences in mean maternal age may contribute to this variation in premutation frequencies [34]. In males the rate ranges from 1/468 to 1/813 [20,35].

Men carrying the premutation allele must mainly be counseled about the risk of FXTAS. This syndrome presents with incomplete penetrance even among premutation carriers with identical CGG-repeat lengths. Approximately 50% of premutation carrier males will develop neurodegenerative symptoms of FXTAS after the age of 50 [36]. The first clinical signs of the syndrome typically appear when patients are in their 50s and 60s, with a mean tremor onset at approximately 60 years and ataxia onset at 62 years [37]. The risk and severity of the disorder appear to be related to the CGG repeat size, with higher risk in larger repeats [38]; nevertheless, a biomarker that predicts the apparition of FXTAS or the protective factors in asymptomatic carriers has still not been identified. Other clinical signs associated with premutation male carriers are neuroendocrine dysfunction, including testosterone deficiency [39], hypertension [40] or bowel and urinary incontinence [41].

Genetic counseling of premutation carrier women must be addressed to the risk for premature ovarian insufficiency, besides the risk for expansion and the FXTAS syndrome. In women, FXTAS is much less common than in men, as many as 16% will develop FXTAS symptoms, it presents a later age of onset and is milder in presentation. The risk for FXPOI in these women increases around 20% with an age of onset before the age of 40 years [28]. Other pathologies associated with females premutation carriers are psychiatric disorders such as depression, anxiety or mood disorders [42-44], migraine [45], immune-mediated disorders, particularly hypothyroidism (15.9%) [36], and fibromyalgia (25%) [7,46,47]. The latter two in particular are even more common among women with FXTAS, with a frequency of 43% and 50%, respectively [7].

Full Mutation Alleles

Full mutations are responsible for FXS, a spectrum of clinical features which includes physical, cognitive and behavioral aspects. All males carrying the full mutation will present with mild to severe intellectual disability and exhibit a variety of maladaptive behaviors overlapping those described for autism spectrum disorders [48,49]. On the contrary, only 50%-70% of women manifest FXS symptoms, albeit in a milder form than men, and some appear to be completely unaffected or exhibit minor neurobehavioral features [50-52]. Despite a common genetic etiology, the clinical presentation of FXS is variable and this variability is related to residual levels of the FMRP due to the presence of CGG expansion size mosaicism, different

methylation levels of the full mutation allele and X-inactivation that leads to a differential pattern of FMRP expression within tissues [51].

On the other hand, there are full mutation carrier males with a standardized IQ score of 70 or higher who are known as high functioning males. In normal males, the 5' CpG island containing the CGG trinucleotide repeat is not methylated, whereas a CGG triplet repeat expands to more than ~200 repeats, this site is methylated and the *FMR1* is transcriptionally silenced [53]. Many mildly affected individuals show mosaic methylation at the *FMR1* promoter.

Regarding their offspring, their daughters will inherit an allele in the premutation range. High functioning males do not present with intellectual disability but recently, FXTAS has been described in a high functioning male [54] and in the case of an unmethylated mosaic (premutation-full mutation) male [55]. The latter suggests that the definition of FXTAS should also include those cases with an expanded allele the size and lack of methylation of which leads to RNA toxicity.

***FMR1* Point Mutations/Deletions**

It has been suggested that patients with a clinical FXS-like phenotype but not carrying the *FMR1* gene full mutation should be screened for *FMR1* mutations [56,57]. It is estimated that *FMR1* point mutations or deletions are responsible for up 1% of FXS cases. Nevertheless, the prevalence of mutations in the *FMR1* coding region is still not well known since the standard FXS protocols only comprise the study of the CGG repeats size. These mutations can be *de novo* or inherited from a carrier mother. A male carrying a point mutation or deletion will always have carrier daughters, who might be affected depending on the X-chromosome inactivation. Carrier females have 50% of risk of transmitting the mutated allele. Within this 50%, all males will be affected and females will be variably affected, depending on the X-inactivation.

REPRODUCTIVE OPTIONS FOR PREMUTATION/FULL MUTATION CARRIERS

Individuals at risk for passing on FXS mutations to their offspring have a variety of pre- and postconception options available. Regardless of the option they choose, women must be advised of any contraindication of these procedures [58]. When offering the reproductive options to a couple at risk, a fertility issue has to be considered since the risk of POF has significant reproductive implications. First of all, the onset of POF is difficult to predict. Secondly, the subtle endocrine perturbations (elevated follicle-stimulating hormone levels) observed in these women decreases the efficiency of ovarian stimulation required for preimplantational diagnosis and finally, there is evidence that premutation carriers may have hormonal changes suggestive of early ovarian aging despite regular menstrual cycles (See Chapter 5).

Prenatal Diagnosis for FXS

Prenatal diagnosis for FXS is possible using chorionic villi or amniotic fluid cells and it depends on several factors, including the physician performing the procedure and patient preference. When the establishment of the sizing of the expansion is sufficient to determine the genotype, the prenatal diagnosis on chorionic villi allows performing a therapeutic abortion at early stages in the pregnancy. On the contrary, the methylation pattern of a full mutation is established after the 14th week of pregnancy, thus the use of a methylation-sensitive method (i.e Southern Blot) is not suitable for early prenatal diagnosis on DNA from chorionic villi [59]. Moreover, the risk of miscarriage may be lower on amniotic fluid cell sampling.

Table 3. Genetic counseling in *FMR1*

Progenitor allele and gender	% expected offspring	Offspring outcome	
		Males	Females
Normal male	No risk	Normal	Normal
Normal female	No risk	Normal	Normal
IA carrier male	Females IA range	Normal	Normal
IA carrier female	50% NA range 50% IA range	Normal	Normal
PM carrier male	Females PM range	Normal	Normal, FXTAS, FXPOI and others
PM carrier female	50% NA range 50%* PM/ FM*	Normal Normal, FXTAS, and others 100% ID	Normal Normal, FXTAS, FXPOI and others 30-50% ID
FM carrier male	females PM range	Normal	Normal, FXTAS, FXPOI and others
FM carrier female	50% NA range 50% FM	Normal 100% ID	Normal 30-50% ID

NA: normal allele, IA: intermediate allele; PM: premutation allele; FM: full mutation allele.

*percentage varies according to the expansion risk indicated in Table 2.

Prenatal diagnosis should be offered to women with premutation or full mutations, but it is not intended for the pregnant partner of a premutation male carrier. These males, nevertheless, should receive genetic counseling about phenotypic risk to their daughters, who will inherit the premutation allele. Neither is prenatal testing intended for intermediate allele carriers. As indicated before, there are no reports of intermediate alleles expanding to full mutations in a single generation. The risk for a female premutation carrier of transmitting the expansion is 50%, and the risk for the maternal premutation to expand to full mutation is proportional to its size and AGG content. Table 3 summarizes the possible outcomes depending on the carrier state of each parent.

The identification of a female fetus with the fragile X full mutation entails a significant challenge for professionals. The probability that a full mutation carrier fetus is affected is around 50-70%, but at present there are no biomarkers to predict this affectation. The diagnosis of a FXS patient requires extending the study to the mother in order to confirm her premutation carrier status.

Preimplantational Diagnosis for FXS

Preimplantation genetic diagnosis (PGD) is a technique based on the genetic analysis of an embryo obtained through in vitro fecundation. The most common option is to perform the genetic study on a day-3 embryo which is then transferred to the uterus. This approach increases the risk of embryo viability due to the biopsy. Further, the possibility of embryo mosaicism has been described at the cleavage stage and self-correction of aneuploidies between the cleavage and blastocyst stages [60]. Polar body biopsies can be used to avoid any misdiagnosis due to embryo mosaicism, although only maternal genetic information is obtained. The third option is to biopsy trophoctoderm cells from blastocysts (5-6 day embryo), which is less invasive and has higher concordance between inner cell mass and trophoctoderm cells [61]. PGD has several advantages over prenatal diagnosis. The diagnosis is performed in the embryo, avoiding the parental stress and the emotional trauma of a termination of pregnancy.

Offspring Renouncement and Adoption

These two options are drastic and are usually rejected by the couples. Therefore they are currently seldom observed as the first choice option by couples at risk that wish to prevent the birth of an affected child.

Donor Germline Cell

Another possible option is egg or sperm donation for female and male mutation carriers, respectively. Based on our experience, around 10% of FXS families chose for a germline cell donation [62]. At present, it is a very good option for premutation carrier females who have been involved in previous prenatal diagnosis and termination of pregnancies. Moreover, given the relatively high prevalence of FXS in the general population, potential gamete donors should be tested for this syndrome.

***FMR1* TESTING GUIDELINES**

Several scientific societies such as the European Molecular genetics Quality Network (EMQN), the American College of Medical Genetics (ACMG), the National Society of genetic Counselors (NSGC) and the American College of Obstetrics and Gynecology (ACOG) have published best practice guidelines for the molecular genetic testing and diagnosis of FXS and other fragile X-associated disorders [18,63-66]. The best practice guidelines for genetic analysis and reporting in FXS, FXPOI, and FXTAS are listed in Table 4. Appropriate *FMR1* molecular testing is very important for optimal genetic counseling in the fragile X-associated disorders due to the particular pattern and transmission of the CGG repeat. Although not being endorsed by current guidelines, screening women without known risk factors to FXS is increasingly being offered. In 2005 Musci and Caughey demonstrated the efficacy and cost effectiveness of prenatal population-based fragile X carrier screening [67].

Table 4. *FMR1* mutation testing recommendations***FMR1* mutation testing is recommended for*:**

Individuals of either sex with intellectual disability, developmental delay or autism
 Individuals who have a family history of FXS
 Women with a family history of *FMR1*-related disorders, including FXPOI
 Women with reproductive or fertility problems associated with elevated levels of follicle stimulating hormone (FSH)
 Individuals with late onset tremor or cerebellar ataxia of unknown origin
 Given the relatively high prevalence of FXS in the general population, potential gamete donors should be tested for this syndrome

*Sherman, 2005; ACOG, 20010.

CONCLUSION

When first described, FXS was a rare X-linked disease responsible for intellectual disabilities in males and females in a lesser percentage. Research into *FMR1* has brought to light the molecular and phenotypic complexity of *FMR1*-related diseases. The first issue to consider is that a FXS patient will always have a premutation carrier mother who should receive genetic counseling. Premutation carrier females have a 50% risk of transmitting a premutation/full mutated allele to their offspring, unlike carrier males who will only transmit the premutation allele. The expansion risk in females depends on the CGG repeats number and the AGG interruptions. Lastly, premutation carriers are at risk not only of having FXS offspring (females) but also of FXPOI (females), FXTAS and other disorders. The complexity of the issues surrounding genetic testing and the management of *FMR1*-associated disorders has increased, and investigation related to this gene covers many aspects, including molecular factors, epigenetic factors, emotional issues or targeted pharmaceuticals. As the knowledge regarding disease causing mechanisms evolves, genetic counselors must have an updated and solid understanding of this genetic condition and the *FMR1*-associated disorders in order to cover all the counseling aspects of these syndromes.

ABSTRACT

Fragile X Spectrum includes three different clinical conditions Fragile X Syndrome (FXS), Fragile X-Associated Tremor and Ataxia (FXTAS), and Fragile X-Associated Premature Ovarian Insufficiency (FXPOI). Treatment of FXS is mainly symptomatic and it is addressed to improve or make disappear some of the more dyscapacitating symptoms like hyperactivity, deficit attention disorder and behavioral problems of language anomalies. Clinical trials are in course focusing on new discovered therapeutical targets (i.e., mGluR). Treatment of FXTAS and FXPOI are also mainly symptomatic and should be individually prescribed and modified depending on the clinical evolution.

INTRODUCTION

Fragile X spectrum includes Fragile X Syndrome (FXS), Fragile X-Associated Tremor Ataxia Syndrome (FXTAS) and Fragile X-Associated Premature ovarian Insufficiency (FXPOI). All three conditions are associated with the CGG trinucleotide expansion in the FMR1 gene on the X chromosome: FXS with more than 200 CGGs (full mutation) and FXTAS and FXPOI with 50 to 200 CGGs (premutation). Patients with FXS and FXTAS are mostly males, although females can also be affected. All three conditions are treated symptomatically, combining pharmacological and non-pharmacological therapies directed at alleviate the main disabling symptoms present in each condition.

FRAGILE X SYNDROME

Fragile X syndrome (FXS) is the most common inherited cause of intellectual disability that affects approximately 1 in 4,000 males and 1 in 8,000 females. Its genetic cause was identified in 1991 and consisted of the expansion of the number of CGG trinucleotide repeats at the FMR1 gene, located on the distal region of the long arm of chromosome X. The normal gene has less than 55 CGGs but when it has more than 55 CGGs it tends to expand when transmitted by the mother to the next generation. Individuals who have between 55- 200 CGGs (premutation) are considered carriers, and those with more than 200 CGGs (full mutation) and have a hypermethylated gene are affected. This methylation leads to the silencing of the FMR1 gene and the subsequent absence, partial or complete, of the FMRP (Fragile X Mental Retardation Protein), considered as the ultimate cause of FXS [1]. The vast majority of FXS males with the full mutation develop intellectual disabilities, which occurs in only 25% of females due to the presence of a normal X chromosome that produces FMRP. However, most females with FXS have learning disabilities and/or emotional and behavior problems [2].

The clinical presentation of FXS is highly variable. In addition to intellectual disability, affected patients have neurodevelopmental problems such as attention deficit hyperactivity disorder, disruptive behavior or autism spectrum disorders. The physical characteristics of FXS include dysmorphic facial features (long face, large and prominent ears and prominent chin), and macroorchidism after puberty [3].

The FMRP Protein and the Synapse

FMRP is expressed ubiquitously in many tissues, predominantly in brain neurons. There it binds to different nuclear mRNAs, including the FMR1 gene mRNA, repressing the translation of the target mRNA to postsynaptic dendritic spines, where its activity is important for synaptic plasticity during transport. Dendritic spines are specialized and rapidly changing protrusions in the neurons whose creation and elimination are essential for learning and memory processing [4]. Microscopic analysis of brain samples of patients with FXS and *Fmr1* knockout mice revealed no gross morphological abnormalities; however, in certain areas of the brain there are spindly dendritic spines, which are interpreted as immaturity and affect adversely the synaptic plasticity [5]. The discovery of a morphological spine phenotype indicates a possible defect in synaptic plasticity in FXS that could result in the intellectual disability phenotype. Whether the abnormal spine morphology is a cause or a consequence of altered signal transmission is currently unknown [6].

The Glutamate Receptor (mGluR) Hypothesis

In the brain, there are two main types of neurotransmitter receptors in the synaptic membrane: metabotropic receptors and ionotropic receptors. Metabotropic receptors (mGluRs) have eight different subtypes (mGluR1-8) which in turn are divided into three groups (I, II and III) according to sequence similarities and pharmacological properties. Group I includes mGluR1 and mGluR5 receptors which activates the Gq protein coupled and phospholipase C.

Group II receptors (mGluR2 and mGluR3) and Group III (mGluR4, mGluR6, and Glu7 Glu8) are coupled to the proteins Gi / Go by inhibiting adenylate cyclase. Ionotropic receptors are ligand-gated ion channels in which the incorporation of a specific ligand induces a conformational change leading to opening of the receiver [7]. The opened receiver allows ion flow across the cell membrane by changing the excitability of the neuron. The main dependent neuronal glutamate ionotropic receptors are: AMPA (isoxazolepropionic amino-3-hydroxy-5-methyl-4-acid), NMDA (N-methyl-D-aspartic acid), and kainate receptors, whose activation produces a fast excitatory neurotransmission [8].

The mechanisms of long-term potentiation (LTP) and long-term depression (LTD) are the most important regulatory mechanisms of neuronal synaptic plasticity, defined as long-lasting changes in synaptic strength accompanied by abnormalities in the size and morphology of dendritic spines. The mechanism of strengthening of LTP produces a connection between presynaptic and postsynaptic neurons. The LTD mechanism is opposite to that of LTP and results in the weakening of synapses, mainly due to a reduction of glutamate-gated ionotropic AMPA-alpha in the postsynaptic membrane [9].

The ‘theory of glutamate receptor (mGluR)’, first published in 2004, tried to explain many aspects of clinical symptoms present in patients with FXS and in the Fmr1-KO mouse, including a higher density and immaturity of dendritic spines compared to normal individuals/mice. This theory stated that internalization of the AMPA receptor is excessive in FXS and likely caused by stimulation of group I mGluRs (mGluR1 and mGluR5). Such stimulation would induce local mRNA translation, resulting in the synthesis of new protein that triggers the internalization of the AMPA receptor, essential for the long-term plasticity of dendritic spines. FMR1 mRNA is also present in the postsynaptic compartment and FMRP is synthesized locally after mGluR activation [10].

On the other hand, FMRP seems to negatively regulate the translation of proteins that are important for the internalization of the AMPA receptor. The exact mechanism by which the FMRP local translation represses mRNA remains unknown. Moreover, phosphorylation and dephosphorylation of FMRP seems play a crucial role in the signaling cascade induced by stimulation of mGluR5 receptors, which stimulate local protein synthesis at the synapses [11].

Since the formulation of the mGluR theory, clinical researchers in FXS have sought the support of the pharmaceutical industry to collaborate in identifying therapeutic strategies aimed at mGluR5 in order to at least partially reverse some of the symptoms of FXS.

The MPEP (2-methyl-6-(phenylethynyl)-pyridine), a negative modulator of mGluR5, can, *in vitro*, counter the excess of activity of the receptor and rescue the loss of AMPA receptors after the loss of FMRP. In FXS animal models, researches have got the pharmacological rescue of audiogenic seizures, behavioral phenotypes and alterations in dendritic spines by using several negative modulators of mGluR5. MGLuR theory has focused research into the basic mechanisms underlying FXS, prompting the search for new therapeutic strategies [12].

The GABA Hypothesis

Besides the mGluR’s hypothesis, researches have suggested that the signaling receptor gamma-aminobutyric acid (GABA) is altered in patients with FXS. GABA is the major inhibitory neurotransmitter in the central nervous system (CNS) and, as such, plays a key role in the modulation of neuronal activity in the brain. GABA mediates its action through two

distinct systems, the ionotropic GABA-A and the metabotropic GABA-B receptors [13]. Many patients with FXS have epilepsy and sleep disorders, conditions associated with the signaling pathway of the GABA receptor. Interestingly, the mRNA encoding GABA-A receptor subunits are targets of FMRP. The *Fmr1*-KO mice have decreased levels of mRNA and protein in various subunits of GABA-A receptor compared to normal animals [14]. These studies support a model in which the FMRP mRNA would regulate the stability of the GABA-A receptor subunits, preventing its degradation by joining these mRNAs *in vivo*. In addition to GABA-A receptors, GABA-B receptors could also be related to FXS, therefore turning into another potential therapeutic target. The GABA-B receptor agonists inhibit the presynaptic release of glutamate and the postsynaptic signaling cascade downstream of mGluR5 [15].

All those studies have demonstrated a dysfunction in the mRNA and protein expression of several subunits of GABA receptors, mechanisms that would be likely involved in the occurrence of the FXS phenotype.

THERAPEUTIC APPROACHES IN FXS

Currently, the treatment of patients with FXS is mainly symptomatic. The two most commonly used medications are stimulants used to improve attention and hyperactivity, and selective inhibitors of serotonin reuptake to reduce the risk of aggression associated with anxiety.

FXS patients are not only treated with pharmacological agents, but also benefit from behavioral therapies for improving emotional and language problems. As already demonstrated in the mouse FXS behavior improves with an enriched environment and therefore this therapy might also be beneficial to humans [16]. Current therapeutic strategies, both pharmacological and non-pharmacological, are aimed at improving the symptoms but do not improve cognitive function. In recent years, new strategies have been developed for therapeutic interventions in FXS based on the theories of mGluR and GABA receptors. Several clinical trials using new designed drugs were initiated to correct the abnormal activity of the mGluR and GABA pathways in FXS [6]. Unfortunately, some of them have been recently discontinued due to the lack of demonstrable improvement.

mGluR5 Inhibitors

The *fenobam* is a potent and selective antagonist of mGluR5 and was the first negative mGluR5 modulator tested in patients with FXS. To test whether it had significant effect on the FXS phenotype, *fenobam* was administered as a single oral dose to twelve affected patients (six males and six females) that the pre-pulse flicker noise (PPI -Pre-Pulse inhibition was measured inhibition of Acoustic Startle-) before and after drug administration. Generally, patients with FXS show decreased PPI compared to healthy control individuals. Six of the twelve patients with FXS showed improvement after treatment with ~~PPI~~ *fenobam*, with no significant adverse effects observed [17].

Although results were promising, it was difficult to draw definitive conclusions because of the lack of a controlled study with placebo, the fact that the patients received only a single dose

of *fenobam*, and the low number of participants enrolled. Other inhibitors are the AFQ056 mGluR5, from Novartis; the STX107, developed by Merck and whose license was issued to Seaside Therapeutics, and the RO4917523, from Hoffman-La Roche [6]. Despite of the results of a preliminary clinical trial with AFQ056 (*Mavoglurant*) in which certain cognitive aspects improved in FXS patients with complete methylation of the FMR1 gene [18], the trial was discontinued by Novartis last April after results of phase IIb/III failed to show demonstrable improvement. Last month, Roche discontinued its trial as well because of negative phase II clinical results.

GABA-A Agonists

GABA-A receptor agonists are currently used as anticonvulsants, antidepressants or anxiolytics. *Benzodiazepines*, which enhance the function of the GABA receptor, are the best-known drugs of this group. Although their anxiolytic effects are useful in patients with FXS have unwanted side effects such as sedation or ataxia, and treatment discontinuation may cause withdrawal symptoms [6]. Besides the selective agonists of GABA-A receptor, neuroactive steroids that allosterically modulate them may be also effective, for example *ganaxolone*, which has a favorable safety profile and may be useful in patients with FXS [19].

The use of inhibitors of GABA-A receptors in patients with FXS is likely to be effective in reducing symptoms such as seizures or sleep disorders.

GABA-B Agonists

Arbaclofen (STX209), a drug proven effective and safe for gastroesophageal reflux disease (GERD), has been used to treat autism spectrum disorders (ASD) in several studies. In an animal model of FXS, *arbaclofen* demonstrated a reversal of behavioral, neurological, and neuropathological features associated with the disease. Results from one double-blind, placebo-controlled study that treated children and adults with FXS have been promising, with signs of improvement in social function, especially in the most severely socially impaired individuals. Two studies, one open-label and one double-blind, placebo-controlled, were also conducted in children, adolescents, and young adults with ASD showing improvements in socialization [20, 21].

Approximately 13-18% of patients with FXS have seizures. The GABA-B and mGluR5 receptors are thought to be involved in the occurrence of audiogenic seizures in *Fmr1*-KO mice. Treatment of these mice with racemic baclofen reduced the incidence of seizures.

Another positive effect of GABA-B receptor agonists could be the reduction of anxiety in patients with FXS. Treatment of *Fmr1*-KO mice with a GABA-B receptors agonist can inhibit audiogenic seizures, supporting the idea that GABA-B receptors are involved in the etiology of FXS [6].

AMPA Agonists

The increased internalization of AMPA receptors in neurons of *Fmr1*-KO mice plays a major role in altering the transmission of signals. CX516 is an ampakine which acts as a positive allosteric AMPA receptor modulator. This compound binds to the AMPA receptor-channel complex and induces a slower deactivation of the receptor, which results in a longer opening time, in a slower disappearance of the excitatory postsynaptic potential, and ultimately to an increased hippocampal LTP, compared to baseline state before administering the drug. Thus, CX516 enhances AMPA receptors after glutamate-mediated synaptic. CX516 has been tested in phase II, randomized, double-blind, placebo-controlled safety for four weeks in adult patients with FXS. Unfortunately no significant or cognitive measures and improvement in behavior were observed. This could be due to the use of low doses, to the CX516 short half-life in humans or, finally, to insufficient time of treatment. In the study, there were only minimal side effects and no serious adverse effects were observed [22].

Theoretically, treatments targeting AMPA receptors could improve behavior in FXS, although the beneficial effects of ampakines have yet to be convincingly demonstrated.

NMDA Receptor Antagonists

Memantine is a non-competitive antagonist of NMDA receptors that can slow the progression of Alzheimer's disease and has been tested to treat Pervasive Developmental Disorders (PDD). In the presence of low levels of synaptic glutamate, binding of *memantine* blocks NMDA receptors, which are unblocked when glutamate levels increase. Besides excessive signaling through mGluR5 is linked to an increased AMPA receptor internalization and to the dysregulation of NMDA receptor activity [23]. Therefore, *memantine* may have positive effects on behavioral problems of patients with FXS.

A clinical trial of *memantine* in six patients with FXS who had a comorbid diagnosis of PDD has been reported. Therapeutic effects were determined by the clinical evaluation of the "Clinical Global Impressions-Improvement" (CGI-I) scale during the time of treatment. The results did not show any significant improvement, although in four of the six patients certain signs of improvement were observed. Furthermore, the study was not a randomized placebo-controlled trial and, therefore, it was difficult to draw valid conclusions [24].

The NMDA receptor may be a target for pharmacological treatment of SXF because some brain regions of the *Fmr1*-KO mice showed impaired NMDA-dependent LTP. However, there is no convincing evidence that NMDA receptor antagonists have demonstrable beneficial effects on behavior [6].

Additional Treatments

Lithium has been used for many years as a mood stabilizer. Most studies that have linked *lithium* with FXS have focused on the path of GSK3. *Lithium* inhibits the activity of GSK-3 β , which in turn inhibits the phosphorylation of microtubule-associated protein 1B (MAP1B). The MAP1B is one of the major targets of the mRNA to which it binds and translationally regulates FMRP. In 2008, a clinical trial with open-label *lithium* was published in FXS patients; although

the test was not randomized and placebo controlled, *lithium* appears that produced beneficial effects as decreased responses of aggression, abnormal vocalization improvement of self-harm and anxiety [25]. In conclusion, *lithium* appears to have beneficial effects on behavior and some cognitive functions but further research, such as long-term placebo-controlled studies are needed to check the effects of *lithium* in patients with FXS.

Minocycline is a tetracycline analog which can inhibit matrix metalloproteinase-9 (MMP-9) and reduce inflammation in the CNS. MMP-9 is an extracellular endopeptidase which breaks down the extracellular matrix proteins acting on synaptogenesis and morphology of dendritic spines. *Minocycline* is thought to act on the mGluR pathway and it has been tested in clinical trials to treat various neurological disorders (stroke, multiple sclerosis and autism). It has also been shown to have beneficial effects on the maturation of dendritic spines in cultured hippocampal neurons of Fmr1-KO mice [26]. A clinical trial of open-label studied the effects of *minocycline* in 50 patients with FXS was recently completed. The results were an improvement in language and behavior [27].

Acamprosate (calcium acetyl-homotaurine) is a commercially available drug used for the maintenance of abstinence from alcohol. This compound appears to have several mechanism of action: antagonist of mGluR5, weak antagonist of NMDA receptors and agonist of GABA-A receptors. Although the mechanism of action of *acamprosate* is not fully understood, a small clinical trial was conducted in three patients with FXS to evaluate the response to treatment with *acamprosate* using the CGI-I scale. After a minimum of 16 weeks of treatment, all three patients improved. Surprisingly, they also showed improvement in language skills. Two subjects experienced nausea. Although these results appear promising, this trial was not placebo-controlled and the number of participants was too small to draw definitive conclusions [28].

Aripiprazole, an atypical antipsychotic that was approved in the USA for the treatment of children and adolescents with autism, has also been tested in patients with FXS. The effect of *aripiprazole* in patients with FXS was assessed by the CGI-I and ABC-I scales. All subjects who completed the study showed significant improvement in irritable behavior [29]. However, the study was not placebo-controlled and therefore the findings were difficult to interpret.

Oxidative stress has been implicated in some psychiatric disorders, including autism. Studies in animal models suggested that in FXS there is an increased sensitivity to oxidative stress, which may alter neuronal and glial function. Indirect evidence was obtained by preclinical treatments of FXS performed using antioxidants. Indeed, chronic alpha-tocopherol treatment normalized free radical production and oxidative stress in the brain of FXS mice, in which it improved many of the behavioral and learning deficits of these mice, such as exploratory behaviors, habituation abnormalities, anxiety responses and contextual fear conditioning [30]. Recently, a phase II randomized, placebo-controlled trial was protocol was designed for children and adolescents with FXS [31].

Chronic melatonin treatment of FXS mice normalized the glutathione levels and prevented lipid peroxidation in the brain and testes of the mice. Moreover, melatonin improved some abnormal behaviors observed in FXS mice such as context-dependent exploratory and anxiety behaviors and learning abnormalities [32]. In a 4-week double-blind, placebo-controlled study with melatonin in 12 children with FXS, ASD or both, results showed a favorable effect (longer) in night sleep duration [33].

Final Remarks

FXS patients are treated with medications to alleviate the symptoms of the disease and/or the behavior problems such as hyperactivity or anxiety. Attempts to discover new drugs for the treatment of patients with FXS are becoming more promising with time due to improved understanding of the molecular mechanisms involved in the pathogenesis of the syndrome. Preliminary trials of new drugs in KO-mice models will be essential before they can be used in clinical trials in humans, although this does not guarantee their success.

To date, several clinical trials have been carried out with promising preliminary results. Nevertheless, others had to be discontinued due to lack of positive results. Hopefully, more trials are currently being conducted or designed with improvements such as randomized double-blind methodology, sufficient number of patients and the use of outcome objective measurements to determine the therapeutic efficacy of the drug. For this, most clinical trials used one or more classic psychological questionnaires, however, the measurements of improvement were based on the likely subjective assessments made by relatives, caregivers and teachers. To ensure objectivity, it is important to develop reliable and objective outcome measurements (i.e.: questionnaires, scales or tests) to determine the true efficacy of the new drug [34]. Fortunately, and despite of some recent disappointing results, a number of clinical-therapeutic trials for FXS and/or ASD are currently in course or being designed.

It is remarkable that in less than 25 years since the discovery of the genetic defect that causes FXS, targeted therapeutic strategies have been already developed, with more or less success, to treat some of the most disabling symptoms of affected individuals. Although curative treatment seems to be far yet, it is likely that in the near future more effective symptomatic treatments will be available for FXS, especially for individuals with ASD. If expectations are met, they will significantly improve their quality of life and of their families.

FRAGILE X-ASSOCIATED TREMOR-ATAXIA SYNDROME (FXTAS)

Fragile X-Associated Tremor-Ataxia Syndrome (FXTAS) is a progressive neurological disease that affects mainly males over 50 who carry a premutation allele (55-200 CGG repeats) in the fragile X gene FMR1. Affected individuals usually have intention tremor, ataxia, signs of parkinsonism, cognitive progressive decline and peripheral neuropathy. Besides, ancillary findings include autonomic dysfunction and psychiatric symptoms such as anxiety, depression and disinhibition [35].

As in FXS, there is no curative treatment for FXTAS, although there are a number of symptomatic therapies that can improve the clinical manifestations in affected individuals. Moreover, there is enough evidence regarding the efficacy of various medications for treatment of other diseases (i.e., Alzheimer diseases) that have important clinical overlap with FXTAS.

The most common therapeutic interventions for FXTAS are listed in Table 1, which includes symptom-based treatments [36]. The drugs are used, basically, to alleviate symptoms related to tremor, equilibrium coordination, parkinsonism, sleep problems, anxiety, mood alterations, memory problems and pain.

FRAGILE X-ASSOCIATED PRIMARY OVARY INSUFFICIENCY (FXPOI)

Primary ovarian insufficiency or premature ovarian failure (POI/POF) is one of the causes of female infertility. POI consists in cessation of menstrual periods, increased levels of FSH and diminished levels of estrogens, all before the age of 40. POI occurs in about 1% of women between 30 to 40 years of age. Fertility of women with POI is severely diminished, but unlike menopause, POI may be accompanied with spontaneous ovarian activity and natural pregnancies [37].

The major causes of POI include autoimmunity, genetic and environmental factors. Among the most common genetic conditions that produce POI is Fragile X premutation, which is present in all female carriers.

Treatment of POI includes hormone replacement therapy to reduce complications due to impaired endocrine function of ovaries, and fertility preservation therapies that include ovarian cortex, oocyte and embryo cryopreservation, oocyte or embryo donation and adoption in women without any ovarian function [38].

Recent research findings in animals and humans showed that neonatal and adult ovaries have some oogonial stem cells (OSCs) that can stably proliferate for months and produce mature oocytes *in vitro*. Studies on the isolation of OSCs from ovaries of aged animals and production of mature normal oocytes in ovaries of young adult animals lead to the recognition of the importance of OSC niche and intraovarian environment on their differentiation to mature, normal oocytes. Therefore, cases of POI that result from defects in ovarian niche and its incapacity to support differentiation and growth of oocytes and also ovarian aging may be reversible in future [39].

These results have offered the opportunity for the application of OSCs as a target for POI therapy, restoration of ovarian function and, subsequently, restoration of normal fertility. However, clinical utility of these cells for treatment requires more evidence to confirm their safety, especially the effects from epigenetic changes during *in vitro* culture, and manipulation of produced oocytes and also resultant offspring.

Table1. Symptom-based treatments for patients with FXTAS

Symptoms	Treatment/Therapy
Tremor	Primidone, beta-blockers, benzodiazepines
Ataxia	Amantadine and physical therapy
Parkinsonism	Carbidopa/levodopa, pramipexole and eldepryl
Cognitive deficits and dementia	Donepezil, rivastigmine, galantamine, memantine
Psychiatric problems	Sertraline, citalopram, escitalopram, duloxetine, mirtazapine, venlafaxine and aripiprazole
Autonomic dysfunction	Bladder incontinency: Tricyclic antidepressants, muscarinic receptor antagonists, cystoscopy with injection of Botox Swallowing difficulties: pyridostigmine bromide
Pain	Antidepressants, antiepileptics, topical analgesics, gabapentin and/or pregabalin

* Modified from Capelli et al., (2010). [36]

CONCLUSION

There is no curative treatment for Fragile X Syndrome. Symptomatic paliative therapies include behavioral and cognitive interventions, speech therapy, occupational and physical therapy, as well as pharmacological treatments. All of them intended to improve intellectual abilities, familial interactions and social integration. Pharmacological treatments should be individualized depending on the age and the intellectual-cognitive level of the affected individual. Treatment for Fragile X-Associated Tremor and Ataxia is also symptomatic, and include physical therapy, psychological and/or psychiatric interventions, and pharmacological treatments. Fragile X Carrier females with Premature Ovarian Insufficiency should be treated by the appropriate specialists. Hormone replacement and fertility preservation therapies are the two main issues that should be addressed.

Chapter 94

PRIVACY AND PROGRESS IN WHOLE GENOME SEQUENCING*

Presidential Commission for the Study of Bioethical Issues

EXECUTIVE SUMMARY

Over the course of less than a decade, whole genome sequencing has progressed from being one of our nation's boldest scientific aspirations to becoming a readily available technique for determining the complete sequence of an individual's deoxyribonucleic acid (DNA)—that person's unique genetic blueprint. With this tremendous advance comes the accumulation of vast quantities of whole genome sequence data and complex questions of how—across a multitude of clinical, research, and social environments—to protect the privacy of those whose genomes have been sequenced. Collections of whole genome sequence data have already been key to important medical breakthroughs, and they hold enormous promise to advance clinical care and general health moving forward. To realize this promise of great public good ethically, individual interests in privacy must be respected and secured.

Large-scale collections of genomic data raise serious concerns for the individuals participating. One of the greatest of these concerns centers around privacy: whether and how personal, sensitive, or intimate knowledge and use of that knowledge about an individual can be limited or restricted (by means that include guarantees of confidentiality, anonymity, or secure data protection). Because whole genome sequence data provide important insights into the medical and related life prospects of individuals as well as their relatives—who most likely did not consent to the sequencing procedure—these privacy concerns extend beyond those of the individual participating in whole genome sequencing. These concerns are compounded by the fact that whole genome sequence data gathered now may well reveal important information, entirely unanticipated and unplanned for, only after years of scientific progress.

Another privacy concern associated with whole genome sequencing is the potential for unauthorized access to and misuse of information. For example, in many states someone could

* This is an edited, reformatted and augmented version of the Presidential Commission for the Study of Bioethical Issues, dated October 2012.

legally pick up a discarded coffee cup and send a saliva sample to a commercial sequencing entity in an attempt to discover an individual's predisposition to neurodegenerative disease. The information might then be misused, for example, by a contentious spouse as evidence of unfitness to parent in a custody case. Or, the information might be publicized by a malicious stranger or acquaintance without the individual's knowledge or consent in a social networking space, which could adversely affect that individual's chance of finding a spouse, achieving standing in a community, or pursuing a desired career path.

Realizing the promise of whole genome sequencing requires widespread public participation and individual willingness to share genomic data and relevant medical information. This, in turn, requires public trust that any whole genome sequence data shared by individuals with clinicians and researchers will be adequately protected. Current U.S. governance and oversight of genetic and genomic data, however, do not fully protect individuals from the risks associated with sharing their whole genome sequence data and information. In particular, a great degree of variation exists in what protections states afford to their citizens regarding the collection and use of genetic data. Only about half of the states, for example, offer protections against surreptitious commercial genetic testing.

Currently, the majority of the benefits anticipated from whole genome sequencing research will accrue to society, while associated risks fall to the individuals sharing their data. This report focuses on reconciling the enormous public benefits anticipated from whole genome sequencing research with the potential risks to privacy of individuals, and the protections that must be foremost in our minds as we focus our policies to facilitate such privacy and progress.

Basic Ethical Principles for Assessing Whole Genome Sequencing

Laws and regulations cannot do all of the work necessary to provide sufficient privacy protections for whole genome sequence data. The Commission has been mindful of how the five ethical principles set out in its first report, *New Directions: The Ethics of Synthetic Biology and Emerging Technologies*, apply to the ethics of whole genome sequencing. These principles—which flow from the ideal of respect for persons—are public beneficence, responsible stewardship, intellectual freedom and responsibility, democratic deliberation, and justice and fairness. This report, *Privacy and Progress in Whole Genome Sequencing*, enlists these principles along with those set forth in the *Belmont Report* (a landmark statement of ethics for research involving human participants). *Privacy and Progress* focuses on recommendations aimed at pursuing and securing the public benefits anticipated from whole genome sequencing while minimizing the potential privacy risks to individuals.

These principles suggest ethically important and practically useful guidelines for whole genome sequencing. Chief among these is the principle of respect for persons, which requires strong baseline protections for privacy and security of data, while public beneficence requires facilitating ample opportunities for data sharing and access to data by clinicians, researchers, and other authorized users. Respect for persons further requires that any collection and sharing of individual data be based on a robust process of informed consent. Responsible stewardship calls for oversight and management of whole genome sequence information by funders, managers, professional organizations, and others. The principle of intellectual freedom and responsibility provides further support for pursuing whole genome sequencing and seeking models for broad data sharing by promoting regulatory parsimony. Democratic deliberation

urges all parties to consider changes to policies and practices in light of the evolving science and its implications for enduring ethical values. Finally, justice and fairness requires that we seek to channel the benefits of whole genome sequencing to all who can potentially benefit, and to ensure that the risks are not disproportionately borne by any subset of the population, including vulnerable or marginalized groups.

Recommendations

Currently we are in a period of intense transition with respect to integrating whole genome sequencing into clinical care, as well as facilitating access to and use of whole genome sequence data for research purposes. Moreover, the challenges we face today are not precisely the same challenges we will face in one, five, or ten years, as genomic technologies continue to develop and mature. Due to the rapid development of technology, we need to craft policies that are flexible and agile enough to ensure that we do not constrain our ability to adapt to evolving technology and social norms related to privacy and access.

Recognizing that ethical obligations reach beyond what is legally enforceable, the Commission examines both the relevant ethical principles and the relevant legal requirements to offer guidance as to what (ethically) *ought* to be done and what (legally) *must* be done. This is the foundation on which the Commission builds its *Privacy and Progress* recommendations.

Strong Baseline Protections while Promoting Data Access and Sharing

Presently, many national and state policies are in place to guard personally identifiable health information and records of participation in research. These policies should apply to all handlers of the data, from those who collect the data, to researchers who use them, to third-party storage and analysis providers (e.g., hosts of cloud computing services). Privacy protections should guard against unauthorized access to, and illegitimate uses of, whole genome sequence data and information while allowing for authorized users of these data to advance individual and public health.

Recommendation 1.1.

Funders of whole genome sequencing research; managers of research, clinical, and commercial databases; and policy makers should maintain or establish clear policies defining acceptable access to and permissible uses of whole genome sequence data. These policies should promote opportunities for models of data sharing by individuals who want to share their whole genome sequence data with clinicians, researchers, or others.

Strong baseline privacy protections require a spectrum of policies starting with data handling through the protection of persons from future disadvantage and discrimination arising from misuse of their whole genome sequence data. It is critical, however, to ensure that privacy regulations allow individuals to share their own whole genome sequence data with clinicians, researchers, and others in ways that they choose.

Recommendation 1.2.

The Commission urges federal and state governments to ensure a consistent floor of privacy protections covering whole genome sequence data regardless of how they were obtained. These policies should protect individual privacy by prohibiting unauthorized whole genome sequencing without the consent of the individual from whom the sample came.

Treating like data alike is crucial to ensuring consistent protections for whole genome sequence information across the United States. Although states should enact genomic policies that are most relevant and important to their constituents, bringing such protections to a minimum standard that addresses privacy—while still allowing individuals to share their own data—would provide just and fair protections regardless of where one happens to reside.

Data Security and Access to Databases

Data privacy requires data security. Data security requires ethical responsibility and accountability from all those who handle whole genome sequence data. It must further be supported by policies and infrastructure to protect safe sharing of data.

Recommendation 2.1.

Funders of whole genome sequencing research; managers of research, clinical, and commercial databases; and policy makers should ensure the security of whole genome sequence data. All persons who work with whole genome sequence data, whether in clinical or research settings, public or private, must be: 1) guided by professional ethical standards related to the privacy and confidentiality of whole genome sequence data and not intentionally, recklessly, or negligently access or misuse these data; and 2) held accountable to state and federal laws and regulations that require specific remedial or penal measures in the case of lapses in whole genome sequence data security, such as breaches due to the loss of portable data storage devices or hacking.

Many observe that absolute privacy is not possible in this, or many other realms. The greater potential for harm is not by virtue of authorized others *knowing* about one's whole genome make-up, but rather through the *misuse* of data that have been legally accessed.

Recommendation 2.2.

Funders of whole genome sequencing research; managers of research, clinical, and commercial databases; and policy makers must outline to donors or suppliers of specimens acceptable access to and permissible use of identifiable whole genome sequence data. Accessible whole genome sequence data should be stripped of traditional identifiers whenever possible to inhibit recognition or re-identification. Only in exceptional circumstances should entities such as law enforcement or defense and security have access to biospecimens or whole genome sequence data for non health-related purposes without consent.

The consent process should communicate limits on access to and use of genomic data to those having their whole genome sequenced in clinical care, research, and consumer-initiated contexts. These policies should apply to the original recipient of the data as well as to all parties who work with the data, from those who collect the sample or data through third-party storage and analysis service providers. Those who work with whole genome sequence data should remain current on regulations regarding data privacy and security.

Recommendation 2.3.

Relevant federal agencies should continue to invest in initiatives to ensure that third-party entrustment of whole genome sequence data, particularly when these data are interpreted to generate health-related information, complies with relevant regulatory schemes such as the Health Insurance Portability and Accountability Act and other data privacy and security requirements. Best practices for keeping data secure should be shared across the industry to create a solid foundation of knowledge upon which to maximize public trust.

Whole genome sequence data not stripped of traditional identifiers are considered “protected health information” and are covered under the Health Insurance Portability and Accountability Act’s Privacy, Security, and Enforcement Rules and the federal Common Rule for protecting human research participants. The same regulations, policies, and ethical guidelines that protect such health information should also be in place to govern the sharing of whole genome sequence data with third-party storage and analysis service providers. Public and the private sector parties should share their lessons learned to promote efficiency and avoid duplicating efforts.

Consent

Not unique to whole genome sequencing, a well-developed, understandable, informed consent process is essential to ethical clinical care and research. To educate patients and participants thoroughly about the potential risks associated with whole genome sequencing, the consent process must include information about what whole genome sequencing is; how data will be analyzed, stored, and shared; the types of results the patient and participant can expect to receive, if relevant; and the likelihood that the implications of some of these results might currently be unknown, but could be discovered in the future. Respect for persons requires obtaining fully informed consent at the outset of diagnostic testing or research.

Recommendation 3.1.

Researchers and clinicians should evaluate and adopt robust and workable consent processes that allow research participants, patients, and others to understand who has access to their whole genome sequences and other data generated in the course of research, clinical, or commercial sequencing, and to know how these data might be used in the future. Consent processes should ascertain participant or patient preferences at the time the samples are obtained.

Recommendation 3.2.

The federal Office for Human Research Protections or a designated central organizing federal agency should establish clear and consistent guidelines for informed consent forms for research conducted by those under the purview of the Common Rule that involves whole genome sequencing. Informed consent forms should: 1) briefly describe whole genome sequencing and analysis; 2) state how the data will be used in the present study, and state, to the extent feasible, how the data might be used in the future; 3) explain the extent to which the individual will have control over future data use; 4) define benefits, potential risks, and state that there might be unknown future risks; and 5) state what data and information, if any, might be returned to the individual.

Each Common Rule agency has its own enforcement authorities to protect research participants. All agencies should work together as they develop clear and consistent guidelines for their informed consent forms. Clinical consent documents for whole genome sequencing will have to address a number of issues specific to whole genome sequencing: an explanation of the science, whether whole genome sequence data collected for clinical applications will be made available for research purposes, and what types of results will be produced through whole genome sequencing. For example, an important unsettled issue is the ethics of reporting incidental findings to individuals— that is, information gleaned from whole genome sequencing research or clinical practice that was not its intended or expected object.

Recommendation 3.3.

Researchers, clinicians, and commercial whole genome sequencing entities must make individuals aware that incidental findings are likely to be discovered in the course of whole genome sequencing. The consent process should convey whether these findings will be communicated, the scope of communicated findings, and to whom the findings will be communicated.

Recommendation 3.4.

Funders of whole genome sequencing research should support studies to evaluate proposed frameworks for offering return of incidental findings and other research results derived from whole genome sequencing. Funders should also investigate the related preferences and expectations of the individuals contributing samples and data to genomic research and undergoing whole genome sequencing in clinical care, research, or commercial contexts.

Individuals undergoing whole genome sequencing in research, clinical, and commercial contexts must be provided with sufficient information in informed consent documents to understand what incidental findings are, and to know if they will or will not be notified of incidental findings discovered as a result of whole genome sequencing.

Facilitating Progress in Whole Genome Sequencing

Currently, large amounts of patient data are being collected in the health care setting, stripped of traditional identifiers, analyzed, and fed into research that might one day improve clinical care. This “learning health system” model both translates advances in health services research into clinical applications and collects data during clinical care to facilitate further advances in research. Learning health system advocates and others support standardized electronic health record systems and infrastructure to facilitate health information exchange so that data can be easily aggregated and studied. Integrating whole genome sequence data into health records in the learning health system model can provide researchers with more data to perform genome-wide analyses, which in turn can advance clinical care.

Recommendation 4.1.

Funders of whole genome sequencing research, relevant clinical entities, and the commercial sector should facilitate explicit exchange of information between genomic researchers and clinicians, while maintaining robust data protection safeguards, so that whole genome sequence and health data can be shared to advance genomic medicine.

Current sequencing technologies and those in development are diverse and evolving, and standardization is a substantial challenge. Ongoing efforts are critical to achieving standards for ensuring the reliability of whole genome sequencing results, and facilitating the exchange and use of these data.

Recommendation 4.2.

Policy makers should promote opportunities for the public to benefit from whole genome sequencing research. Further, policy makers and the research community should promote opportunities for the exploration of alternative models of the relationship between researchers and research participants, including participatory models that promote collaborative relationships.

Respect for persons implies not only respecting individual privacy, but also respecting research participants as autonomous persons who might choose to share their own data. Public beneficence is advanced by giving researchers access to plentiful data from which they can work to advance health care. Regulatory parsimony recommends only as much oversight as is truly necessary and effective in ensuring an adequate degree of privacy, justice and fairness, and security and safety while pursuing the public benefits of whole genome sequencing. Therefore, existing privacy protections and those being contemplated should be parsimonious and not impose high barriers to data sharing. While the Commission supports the intellectual freedom this access will encourage, clinicians and researchers must also act responsibly to earn public trust for the research enterprise.

Public Benefit

Thousands of citizens have participated in whole genome sequencing research personally, and all citizens help to support government investment in whole genome sequencing through their general participation in and support of our political system. Therefore, all citizens should have the opportunity to benefit from medical advances that result from whole genome sequencing.

Special caution should be taken on the part of researchers to ensure that their participants accurately reflect as much as possible the rich diversity of our population. Different groups have genomic variants at different frequencies within their populations, and sufficiently diverse data must be collected so that advances arising from whole genome sequencing can be used for the benefit of all groups.

Recommendation 5.1.

The Commission encourages the federal government to facilitate access to the numerous scientific advances generated through its investments in whole genome sequencing to the broadest group of persons possible to ensure that all persons who could benefit from these developments have the opportunity to do so.

Government investment in genomic research has resulted in public benefit through improved health care and in economic return on investment. The principle of justice and fairness requires that the benefits and risks of whole genome sequencing be distributed equitably across society. Research funded with taxpayer contributions should benefit all members of society. To these ends, researchers should be vigilant about including individuals from all sectors of society in their studies, so that research findings can be translated widely into improved clinical care. The federal government should follow through on its investment

in research and assure that the discoveries of whole genome sequencing are integrated with clinical care to benefit the health of all.

INTRODUCTION

The Potential of Whole Genome Sequencing

In 1996, Retta Beery gave birth to apparently healthy twins Alexis and Noah.¹ It soon became clear, however, that something was wrong; the twins cried nonstop and had developmental problems. Over the next two years, Retta and her husband Joe endured the physical, emotional, and financial costs of visiting numerous specialists, putting their young twins through countless tests, and having their children undergo surgery. None of these steps provided results or solutions.

In 1998, the twins were diagnosed with cerebral palsy and a related course of treatment was outlined. Although the treatment yielded some symptomatic improvement, Retta felt that the diagnosis was incorrect. In 2002, the Beerys were starting to look at wheelchairs and feeding tubes when Retta, after four years of research, stumbled upon an article on DOPA-responsive dystonia (also known as Segawa's dystonia) and suspected that this was the disease that the twins had. The Beerys contacted a specialist, and after a physiological test the twins were diagnosed with Segawa's dystonia. They began a new course of treatment to increase brain dopamine, which yielded a dramatic improvement in their health.

In 2009, Alexis developed breathing problems and was forced again to endure multiple emergency room visits and a battery of tests and visits to specialists. In August 2010, the Beerys went to Baylor College of Medicine for diagnostic whole genome sequencing. By November, Alexis's and Noah's whole genomes had been sequenced. Their data were compared to other whole genome sequences in databases, such as the Baylor Human Genome Sequencing Center's database, to reveal what was unique about the Beery twins' genomes. Clinicians now had answers for the family. The geneticists had uncovered an extremely rare and only recently recognized genetic cause of DOPA-responsive dystonia producing a deficiency of not only dopamine but also serotonin production in the brain. Armed with this new information, the Beerys returned to their neurologist, who amended the treatment regimen for Alexis and Noah with an over-the-counter supplement. Within a month, Alexis's breathing problems disappeared.

As a result of that final piece of the puzzle—the information provided by whole genome sequencing—Alexis is able to breathe normally and can now even compete in sports. Both children have a definitive diagnosis, and are expected to live long, healthy lives.

THE CHALLENGE OF PRIVACY

Victoria Grove's sisters struggled with a difficult genetic diagnosis: alpha-1 antitrypsin deficiency. The genetic illness meant that her sisters' bodies did not make enough of a protein that protected their lungs and liver from damage, which could lead to emphysema and liver disease.

Victoria wanted to help them, and in 2004 agreed to enroll in a research study of families with alpha-1 antitrypsin deficiency. *"I just knew I didn't have it, so I signed up for the study."* But the tests came back positive—Victoria had the same genetic mutation as her sisters. She did not yet have any symptoms, and wanted to keep her test results private, so she did not tell her doctor.

In 2005, Victoria got tested again to confirm the research study results. She used a private company and had the results sent directly to her. Victoria's second test came back positive, and she chose again not to send the results to her doctor, fearing that the information would be included in her medical record. Victoria worried that this information could lead her insurance company to drop her coverage or charge her higher rates. Victoria kept her genetic results private for nearly three years.

The pivotal moment came when Victoria felt she was coming down with a bout of pneumonia but could not convince the nurse practitioner who saw her to order the X-ray necessary to prescribe antibiotics. Victoria went home without antibiotics, her condition worsened, and she called back a few days later. The nurse asked Victoria to come in again, but Victoria told them she could not drive across town in the snowstorm that had immobilized the city. She could, however, get to a pharmacy near her house if the office called in the antibiotics. The nurse on the phone insisted this was not possible. *"My emotions just took hold and I cried 'I have alpha-1 and I need that antibiotic,'"* Victoria said. *"At that point the cat was out of the bag."*

Today Victoria gets regular treatments for her condition. She recognizes that fear kept her from providing her clinicians with crucial information. Still, she can't convince either her brother or her son to get tested for alpha-1. Victoria says both men are aware that there is federal protection from discrimination in employment and health insurance, but fear that these laws will not provide sufficient protection. Her son already has to buy his own health insurance; he does not want any information in his medical record that could jeopardize his job or his access to health insurance. *"I can imagine in a job situation, it's expensive to take on someone if they're ill. And you can always get rid of people for other reasons. I assume that's going on."*

Whole genome sequencing offers great promise of medical advances that could benefit all of society, but this promise is tempered by the concerns of individual privacy. This tension between medical progress and the risks to privacy from whole genome sequencing is the subject of this report. To use whole genome sequencing to discover the changes in deoxyribonucleic acid (DNA) that underlie disease, scientists and clinicians must have access to whole genome sequence data from many individuals (for the definitions of scientific terms used in this report, see Appendix I: Glossary of Key Terms). Continued advances therefore depend on large numbers of individuals who are willing to share their whole genome sequence data for research purposes. Further, scientists are better able to make connections between variations in whole genome sequence data and specific diseases when additional health and demographic information accompanies these data. But this additional information might make it easier to identify an individual and discover his or her private health information.² Thus, while society stands to benefit from advances in improved medical treatment and diagnosis from whole genome sequencing, the privacy risks associated with sharing whole genome sequence data fall predominantly on the individuals themselves.

Whole genome sequencing is a technique that determines the complete sequence of DNA in an individual's cells (See Figure 1. For more information regarding the science of whole

genome sequencing, see Appendix II: Genetic and Genomic Background Information). Whole genome sequencing reveals the genetic blueprint for a person, generating information on every gene in the nucleus of one’s cells. Each person’s DNA is unique, and changes in DNA can lead to disease. The ability to link variations in DNA with health and disease outcomes, a process still in its infancy, holds promise for substantial public benefit.³ These benefits have the potential to alter the way we treat cancer, heart disease, diabetes, Alzheimer’s disease, schizophrenia, and countless other illnesses.

The Commission believes that the ethical principles and recommendations in this report should not be limited to whole genome sequencing. Whole genome sequencing is the focus of this report because of its current promise to advance health. The ideas in this report, however, apply broadly to all studies using large-scale genetic and genomic data and information, including whole exome sequencing, genome-wide SNP analysis, and other large-scale genomic studies. The tools used to decipher and study whole genomes are evolving rapidly, and it is not clear what additional technologies will emerge in the near future. What is clear is that all current genetic and genomic research can be measured against the ethical principles and recommendations described in this report, and the Commission is optimistic that its recommendations will specifically accommodate future advances in large-scale sequencing and analysis.

Figure 1. The Structure of DNA.

TERMINOLOGY

Whole genome sequencing: determining the order of nucleotide bases—As, Cs, Gs, and Ts—in an organism’s entire DNA sequence

Whole genome sequence data: the file of As, Cs, Gs, and Ts that results from whole genome sequencing

Whole genome sequence information: facts derived from whole genome sequence data, such as predisposition to disease

Genomics: the study of all the DNA (the genome) in an individual, and how parts of the genome interact with each other and the environment

Genetic test: a discrete test that examines a specific genetic location or a single gene, such as the test for Huntington’s disease

Genotyping: analyzing a handful to thousands of discrete variants across the genome (i.e., more than a discrete genetic test, but less than whole genome sequencing)

For additional terminology, please see Appendix I: Glossary of Key Terms and Appendix II: Genetic and Genomic Background Information.

Current clinical uses of DNA information are limited mostly to specific genetic tests. If clinicians suspect a particular disease with a known genetic cause, such as Huntington’s disease, they can order a genetic test looking at one specific gene among the more than 20,000 genes in the human genome. These tests examine only a few of the whole genome’s three billion pairs of building blocks. The price of sequencing a whole genome is dropping rapidly, however, and soon it will be less expensive to sequence an entire genome than to perform a few individual genetic tests. Once this happens, whole genomes might be sequenced in lieu of discrete genetic tests, and such information can be stored in a patient’s medical records. Then, if a clinician would like to find out something about a patient’s DNA in the future, he or she could examine the whole genome sequence data already stored in that patient’s record. For example, a patient’s response to a particular dose of warfarin, a drug that helps prevent blood clotting, is partly dependent on his or her genetic makeup. A clinician with access to a patient’s whole genome sequence can use it to identify drug sensitivity and reduce the time required to achieve the optimal dosage.⁴

The sheer amount of information contained in our genomes is what makes whole genome sequence data different from other medical information. Our whole genome sequence data can reveal predispositions to diabetes, cancer, or psychiatric conditions. The data can also reveal variations in DNA that are not yet understood. For example, an apparently healthy individual could be missing a small piece of DNA. The person seems healthy, but will that variant cause a problem in the future?

Over 20,000 individual human genes have been identified. A major recent advance by the National Institute of Health’s (NIH) Encyclopedia of DNA Elements (ENCODE) project greatly enhanced our knowledge of the function of the genome through a flurry of scientific publications, finding that 80 percent of the genome has a “biochemical function.”⁵ For years,

that number had stood at 10 percent.⁶ Eric Lander, president of the Broad Institute, compared the results of the Human Genome Project, which sequenced the first full human genome, to a picture of the Earth from space, and compared the ENCODE project to Google Maps. The ENCODE Project is a major step toward demonstrating the function of the whole genome sequence that was determined in the Human Genome Project, much like Google Maps can refine a snapshot of the Earth by showing traffic, alternate routes, and the location of landmarks.⁷ The function of 20 percent of the non-coding regions—regions of DNA that do not contain specific instructions for making proteins—is still unknown, but these regions might have functions that are yet to be determined.

Unlike genetic testing—which looks at the specific parts of the genome to reveal a variant at a specific location of a single gene indicating a particular disease—whole genome sequencing reveals an individual’s entire genome, including all variants within the genome. These variants are changes in the DNA sequence and range in size from small changes like a single base pair change, to larger changes such as a deletion of a portion of the DNA strand. As more information about our genomes becomes available, variants that might be revealed by whole genome sequencing include: specific known disease variants; variants of unknown significance (e.g., an unknown variant in the region that increases risk for heart disease); nonmedical genetic traits, including hair and eye color; carrier status variants, including variants that do not cause disease in the individual but could be passed on, such as mutations for hemophilia or cystic fibrosis; susceptibility genes, such as those that slightly increase susceptibility to diabetes, heart disease, or some cancers; and genes for conditions with late onset that will not affect an individual until much later in life, such as Alzheimer’s disease and Huntington’s disease.⁸ Only a small number of the genetic variants that whole genome sequencing might reveal have yet been studied enough to substantiate their connection to disease.⁹

“And so having the genome may be not incredibly powerful right now, but it opens the door to outrageous rates of discovery, which I’m pretty certain are going to happen over the next five to ten years.”

Leonard D’Avolio, Associate Center Director for Biomedical Informatics, Massachusetts Veterans Epidemiology Research and Information Center, Department of Veterans Affairs, Instructor, Harvard Medical School. (2012). Genomic Privacy, Data Access, and Health IT. Presentation to PCSBI, May 17, 2012. Retrieved from [http:// bioethics.gov/cms/node/713](http://bioethics.gov/cms/node/713).

Whole genome sequencing also raises many potential concerns for individuals. One might shoulder the burden of knowing medical information regarding future adverse health conditions for which there is currently no treatment. Whole genome sequencing raises concerns about our privacy as well. Just as patients would not want to give anyone access to their medical record, many people might not want others to have access to their whole genome sequence data and information. With unauthorized access comes concerns about misuse of information. For example, someone could pick up a discarded coffee cup and send a sample of saliva—which contains DNA—from the rim of the cup to a commercial sequencing entity in an attempt to discover an individual’s predisposition to neurodegenerative disease. The information might then be misused by publicizing it in a social networking space, which could derail that

individual's chance of finding a spouse, achieving standing in a community, or pursuing a certain career path.

To yield medically useful information, an individual's genomic sequence data needs to be coupled with clinical information about disease and compared to other genomic sequence data. Further, genomic research is complex because each person's DNA naturally has thousands of variants, and the vast majority of these variants do not cause disease. The research and clinical power of whole genome sequencing lies in being able to compare a large number of whole genome sequence data sets that are linked with relevant health and disease states. This type of study allows researchers to identify sequence variations and associations between whole genome sequence variations and disease. For this reason, scientists need whole genome sequence data to be linked to clinical, laboratory, and socio-demographic data. This linking can be done by entering only relevant information (e.g., disease state or symptoms) and excluding personally identifiable information, such as an individual's name or address; but without access to relevant medical data, links between whole genome sequence variations and disease could not be identified.

Recent technological advances have facilitated storing and sharing of whole genome sequence data. Whole genome sequence data and associated health information can now be stored in genomic databases and biorepositories that contain digital information and physical samples, respectively, from large numbers of persons. By using these resources, researchers will have the volume of data they need to advance medical understanding for the public good through genomics. However, this data storage and sharing raises its own questions: How does one securely store these huge data files? Who should have access to these data files? How can these data be used productively, and how might they be misused? What constitutes "misuse"? What should the penalties be for misusing these data? The summation of all these issues—the unknowns, privacy, consent, data security, and data storage involved in whole genome sequencing—will require careful and sustained ethical attention.

This report delves into two crucial questions: What information about an individual's whole genome should remain private, and when should it remain private? The Commission explores how, when, and why genomic information should remain subject to clear rules of confidentiality, secrecy, information security, decisional autonomy, and freedom from unwanted intrusion out of respect for individuals. Without trust in the confidentiality and security of the data, individuals could be less likely to participate in research. Conversely, with well-founded trust that their sense of privacy will be honored, individuals are treated with the respect to which they are entitled and might be more likely to contribute to the research enterprise that promises important public benefits.

This report therefore aims to pursue and secure the public benefit anticipated from whole genome sequencing while minimizing the potential privacy risks to individuals. The recommendations draw upon the principles that flow from the ideal of respect for persons, and are set forth in the *Belmont Report*, a landmark statement of ethics for research involving human participants, and those outlined in the Commission's first report *New Directions: The Ethics of Synthetic Biology and Emerging Technologies*.¹⁰

The Promise of Whole Genome Sequencing

Whole genome sequencing can help researchers and clinicians better understand the unique qualities of a disease, and, especially when combined with other information, might help select treatment methods.¹¹ Researchers already have been able to help clinicians aid some children born with rare birth defects by sequencing and analyzing their whole genomes to diagnose and treat their illnesses.¹² Researchers are also teaming up with clinicians in using whole genome sequence data to advance personalized medicine, including predicting an individual's risk for a heart attack or determining the best dosage of medication for an individual.¹³ Researchers recently determined a fetal whole genome sequence using a blood sample from the mother, an innovation that could soon reach the clinic.¹⁴ And this is only the beginning of the whole genome sequencing era, which has the potential to revolutionize medicine.

In 2000, the cost of sequencing a single human genome was estimated to be 2.5 billion dollars; it is anticipated that this cost will soon be \$1,000. As the cost falls, whole genome sequencing will be increasingly integrated into clinical care. Clinicians can—and many will—incorporate whole genome sequence information into the clinic to promote the practice of personalized medicine.¹⁵ Nevertheless, little has been written about the ethical concerns of integrating whole genome sequencing into the clinical context, which is particularly problematic given the speed with which this could occur.¹⁶ The Commission therefore presents its recommendations mindful of the changing uses and implications of whole genome sequencing. Although this report focuses on issues related to privacy and sharing of whole genome sequence data, the Commission recognizes that another important unsettled issue is the ethics of reporting incidental findings to individuals—that is, information gleaned from whole genome sequencing research or clinical practice that was not its intended or expected object. The Commission plans to take up the issue of incidental findings in the future.

Privacy Concerns

At age 13, Brian Hurley learned from an ophthalmologist that he had retinitis pigmentosa and that at some unknown point in his life he would go blind. During high school, Brian learned about careers in law and thought this was something he could do well, regardless of eyesight. When he started law school, however, he realized he did not like it. Brian needed to find something he could do and wanted to do—not just something a blind person was considered capable of doing.

Brian felt tremendous pressure to resolve his career path before he lost his vision: “In the beginning of a career, you try to figure out what you are good at and hopefully enjoy, but I was more concerned about could I do it well when blind.” Brian spent hours online searching for careers that might work, and successful blind professionals that he could use as role models. “It was like having a time bomb inside of me,” Brian said.

After college, Brian experienced a steady decline in his peripheral vision. At age 27, Brian stopped driving. During this time, Brian's actual symptoms did not match the decline of his emotional state. Brian said he was so panicked that it took the joy out of his last few years before becoming legally blind. “If you took my mental condition, I might as well have been blind already.”

Then, at 33, Brian lost the majority of his eyesight. “The irony is, anticipation was much worse than the actual loss. It was a relief to stop worrying when the loss would occur.”

Today, at 39, and relieved of the anticipation, he enjoys his current role as a Public Affairs Program Director. Brian refuses to let his vision loss be an obstacle to his professional and personal goals.

Brian recently learned of the eyeGENE® program at the National Institutes of Health. He wants to help with eye research—specifically research related to retinitis pigmentosa. He knows research is important and wants to contribute his data to help others. He does not, however, want his whole genome sequenced in the course of participating in research.

Before enrolling in the eyeGENE® program, Brian spent three days with a lighted magnifier and 20 pages of consent forms to ensure that researchers would not sequence his entire genome and that they will not divulge findings about other diseases to him. Having lived with one time bomb, Brian understands its collateral damage. He never wants to carry that burden again. In his situation, Brian feels that having less information is better.

With regard to whole genome sequence data, privacy concerns are more complex than a simple decision about whether to undergo whole genome sequencing and, if so, whether the data should be included with an individual’s medical record. Individuals might have good reason for wanting to share particular parts of their genomic data—such as for the purposes of research— but might also want to limit the extent to which others can access these data.

The prevention of unauthorized use or disclosure of medical information about specific individuals has long been a serious ethical concern. Whole genome sequencing dramatically raises the privacy stakes because it necessarily involves examining and sharing large amounts of biological and medical information that is not only inherently unique to a single person but also has implications for blood relatives. Genomic information is inherited and determines traits like hair and eye color. Unlike a decision to share our hair or eye color, which does not reveal anything about our relatives that is not observable, a decision to learn about our own genomic makeup might inadvertently tell us something about our relatives or tell them something about their own genomic makeup that they did not already know and perhaps do not want to know. More than other medical information, such as X-rays, our genomes reveal something both objectively more comprehensive and subjectively (to many minds) more fundamental about who we are, where we came from, and the health twists and turns that life might have in store for us.

The fact that whole genome sequence information is uniquely connected to our conceptions of self is what could cause the inappropriate disclosure or misuse of this information to be so harmful. In theory, whole genome sequence information could be used to deny financial backing or loan approval, educational opportunities, sports eligibility, military accession, or adoption eligibility.¹⁷ Disclosing genomic information could affect the opportunities available to individuals, subject them to social stigma, and cause psychological harm. The full extent of what whole genome sequencing can reveal is unknown, but we know that having one’s whole genome sequenced today could reveal genetic variants that increase the risk for certain conditions such as Alzheimer’s disease, which many people either do not want to know about themselves or others to know about them.

“[H]arm is not the act...of distributing data. Harm comes from actions that are taken once the data have been distributed.”

John Wilbanks, Founder, Consent to Research; Senior Fellow, Kauffman Foundation; Research Fellow, Lybba. (2012). Privacy II – Control, Access and Human Genome Sequence Data. Presentation to PCSBI, February 2, 2012. Retrieved from <http://bioethics.gov/cms/node/659>.

It is understandable, therefore, that whole genome sequencing heightens concerns about how unauthorized disclosure can threaten one’s individual privacy. But determining what privacy requires in the whole genome context is not straightforward. In the legal context, privacy is multidimensional and includes physical, informational, decisional, proprietary, associational, and intellectual aspects.¹⁸ While there is no consensus definition of privacy, in this report we consider privacy to be a general concept that includes confidentiality, secrecy, anonymity, data protection, data security, fair information practices, decisional autonomy, and freedom from unwanted intrusion.¹⁹ Whole genome sequencing calls for serious consideration of each of these components and their related ethical concerns. It also is important to recognize at the outset that, in some significant respects, parts of our genomic information are not and cannot be wholly private. When we routinely provide a blood sample in a clinical exam, decide to submit a DNA sample to be used in research, or unintentionally leave behind traces of DNA on a coffee cup that we discard in a public waste bin, we are providing some other individuals the opportunity to learn something about us.

While doing everything possible to prevent any use of whole genome sequence data certainly would provide strong privacy protection, it would fail to allow the anticipated public benefit that is to be achieved by sharing whole genome sequence data and advancing science. Because preventing all whole genome sequence data sharing would stifle potentially life-saving and life-enhancing medical progress, we must focus on how best to protect confidentiality of data, ensure security of information from unauthorized access and uses, preserve decisional autonomy as to possible uses, and guarantee the freedom of individuals from unwanted and unwarranted intrusion.

Policy and Governance

“If you sequence people’s exomes you’re going to find stuff,” said Gholson Lyon, a physician and researcher previously at the University of Utah, now at Cold Spring Harbor Laboratory.

As part of his research, Dr. Lyon worked with a family in Ogden, Utah. Over two generations, four boys had died from an unknown disease with a distinct combination of symptoms—an aged appearance, facial abnormalities, and developmental delay.

Dr. Lyon sought to identify the genetic cause of this disease, and collected blood samples from 12 family members who had signed consent forms. The family members understood these forms to mean that they would have access to their results.

Dr. Lyon conducted exon capture and sequencing of the X chromosome—a process that analyzes specific regions of the X chromosome and is a less expensive alternative to whole genome sequencing—to analyze the blood samples. Dr. Lyon and his colleagues identified a genetic mutation, and named the disease Ogden Syndrome after the family’s hometown.

After Dr. Lyon and his team identified the genetic basis of Ogden Syndrome, one of the family members contacted him. This young mother of one daughter had submitted a blood sample for Dr. Lyon's research. She had not been pregnant at the time, but was now four months pregnant with her second child. She knew that she was carrying a boy and wanted to know if she was a carrier of the mutation. She wanted to be able to mentally and emotionally prepare herself and her family.

By reexamining his research data, Dr. Lyon was able to see that the expectant mother was a carrier of Ogden Syndrome. This meant that her son had a 50 percent chance of being born with the disease. Dr. Lyon could not, however, legally share this important information with the family because he had conducted the original sequencing in a research laboratory that had not satisfied federally mandated standards designed to ensure the accuracy of clinical genetic results.

Instead, Dr. Lyon worked to have the mutation validated at a laboratory that satisfied those federal standards; this involved overcoming substantial bureaucratic hurdles and other obstacles that held up the process. During this time, the baby boy was born and died of Ogden Syndrome at four months of age. While knowing the results would not have changed the outcome, Dr. Lyon feels he should have been able to do more for the family.

Dr. Lyon has become an outspoken advocate for conducting whole genome sequencing in laboratories that satisfy the federal standards so that researchers can return results to participants, if appropriate. Dr. Lyon wants clear guidance for laboratories conducting genetic research and clear language in consent forms that clarifies the results that participants should expect to have returned from the researchers.

Realizing the promise of whole genome sequencing requires widespread public participation and individual willingness to share genomic data and relevant medical information. This requires public trust that any whole genome sequence data shared by individuals with researchers and clinicians will be adequately protected. Individuals must trust that their whole genome sequence data will not be either intentionally or inadvertently disclosed or misused. Current U.S. governance and oversight of genetic and genomic data, however, do not fully protect individuals from the risks associated with sharing their whole genome sequence data and information.

The Genetic Information Nondiscrimination Act of 2008 (GINA) is the leading federal protection of genetic information, but it offers only prohibition of genetic discrimination in health insurance and employment. GINA does not regulate access, security, and disclosure of genetic or whole genome sequence information across all potential users, nor does it protect against discrimination in other contexts. U.S. state laws on genetic information vary greatly in their protections of individuals, and they also fail to provide uniform privacy protections. In an era in which whole genome sequence data are increasingly stored and shared using biorepositories and databases, there is little to no systematic oversight of these systems.

Ethical Principles

Laws and regulations cannot do all of the work necessary to provide sufficient privacy protections for whole genome sequence data. Individuals who obtain their whole genome sequence data also have a responsibility to thoughtfully consider to what extent they ought to

act to protect their own privacy beyond current legal protection when considering whether to share their data and information publicly.

In its previous reports, the Commission established an ethical framework for considering the implications of scientific advances, including emerging technologies, that can be applied in similar situations. That framework outlines principles developed to apply particularly to emerging biotechnologies that do not directly involve human therapy or human experimentation. These guiding principles are 1) public beneficence, 2) responsible stewardship, 3) intellectual freedom and responsibility, 4) democratic deliberation, and 5) justice and fairness.

As biomedical science has evolved over time, the lines between clinical care, human research, and research not involving human participants have become blurred. The principles developed by this Commission, which flow from the concept of respect for persons, are described in detail in *New Directions: The Ethics of Synthetic Biology and Emerging Technologies*, and also apply when considering the ethics of whole genome sequencing.²⁰ As applied to the science of whole genome sequencing, these principles, along with the principle of respect for persons, guide us to focus on pursuing public benefit while minimizing both personal and public risk.

Respect for Persons

Respect for persons provides a strong, enduring, and widely accepted foundation for this report's recommendations for protecting individual privacy in the pursuit of public benefit. As set forth in the *Belmont Report*, respect for persons requires one to give great "weight to autonomous persons' considered opinions and choices while refraining from obstructing their actions unless they are clearly detrimental to others."²¹ The *Belmont Report* recognizes that not all persons can act as autonomous agents, and makes clear that there are special responsibilities to those who cannot.

Public Beneficence

Public beneficence asks us to pursue and secure public benefits and minimize personal and public harm. It encompasses society's duty to promote activities that have great potential to improve the public's well-being.²² Public beneficence also supports scientific enterprises that benefit society by increasing economic opportunities.

Responsible Stewardship

Responsible stewardship calls upon governments and societies to proceed prudently in promoting scientific advancement by taking into account the interests and needs of those who are not in a position to represent themselves such as children, the mentally ill, future generations, or individuals that may be unaware of risks. Responsible stewardship expresses a shared obligation to act in ways that demonstrate respect for such individuals. Emerging technologies present particularly profound challenges for responsible stewardship because our understanding of their potential benefits and risks is incomplete and uncertain.²³ This makes it all the more important that we take great care not to make choices that have a substantial chance of causing irreversible harm to current or future generations.

Intellectual Freedom and Responsibility

Intellectual freedom grants scientists, acting responsibly, the right to use their creative abilities to advance science and the public good. Sustained and dedicated creative intellectual exploration produces much of our scientific and technological progress. Intellectual responsibility, the complementary part of this principle, calls upon scientists to adhere to the ideals of research; to avoid harm to others; and to abide by all applicable policies, rules, and regulations. Institutions, policies, and practices of a free society—along with the many citizens who support them—collectively provide the means for scientists to do their work, and the culture that recognizes and upholds intellectual freedom. As a result, scientists bear profound collective responsibility to society.²⁴

The Commission endorses the principle of regulatory parsimony, which encourages fostering an achievable balance of intellectual freedom and responsibility. Regulatory parsimony calls for “only as much oversight as is truly necessary to ensure justice, fairness, security, and safety while pursuing the public good.”²⁵ In this spirit, policy makers are obligated to avoid restrictive rules that offer few benefits and hinder progress in science, medicine, and health care.²⁶

Democratic Deliberation

Democratic deliberation is an approach to collaborative decision making that embraces respectful debate of opposing views and active participation by citizens. Democratic deliberation warrants engaging the public and fostering dialogue among the scientific community, policy makers, and persons concerned with the issues raised by scientific progress.²⁷ The principle of democratic deliberation acknowledges that while decisions must eventually be reached, those decisions need not (and often should not) be unalterable, particularly when subsequent developments warrant additional examination. It is in the spirit of democratic deliberation that the Commission was created, has undertaken its work in publicly open meetings, and offered all of its reports to the President and members of the public.

Justice and Fairness

The principle of justice and fairness relates to the distribution of benefits and burdens across society. A commitment to justice and fairness is a commitment to ensuring that the unavoidable burdens of technological advances do not fall disproportionately on any particular individual or group, and that the benefits are widely and equitably distributed.²⁸ The principle of justice and fairness counsels that the numerous scientific advances stemming from investments in science and medicine should be made accessible to the broadest possible number of persons, consistent with the ability to advance science and medicine for the true benefit of the public.

The Commission’s Process

In concert with the principle of democratic deliberation, the Commission invited experts from the public and private sectors to inform their deliberations. Over the course of four public meetings, speakers addressed issues of privacy, consent, data security, access to whole genome sequence data, views of the patient advocacy community, and relevant philosophical topics (for

a complete list of Commission speakers, see Appendix III: Guest Presenters to the Commission Regarding Privacy and Whole Genome Sequencing). The Commission also posed a data call to the 18 Common Rule departments and agencies, asking them to identify relevant statutes, agency regulations, guidance documents, and policies that govern privacy and access to genetic information generally and whole genome sequence data specifically.²⁹ Finally, a Request for Information was published in the *Federal Register* that elicited many thoughtful comments from individuals and professional societies.³⁰

The Commission identified the field of whole genome sequencing as an important topic for consideration because this rapidly advancing technology raises many ethical issues that have not been fully addressed. After careful consideration of where it could make the greatest contribution at the present time, the Commission chose to focus on privacy rather than address ethical issues that are currently under consideration or have been addressed by other high-level groups or federal agencies, including commercial genetic testing and other important and controversial topics relevant to whole genome sequencing.³¹

In focusing on the potential risks to individuals' privacy, the Commission also recognizes the anticipated societal benefit of the scientific and medical applications of advances in whole genome sequencing. Reconciling these goals means addressing the competing concerns of ensuring confidentiality of whole genome sequence data, granting access to and use of these data, and empowering participants who want to share their data without weakening privacy protections for others. The Commission reviewed rules and regulations already in place that protect privacy and prevent discrimination based on genetic information (currently there are no state or federal laws explicitly addressing whole genome sequence data), and heard testimony about the technological security systems used to protect whole genome sequence data. The Commission heard from experts about the ways whole genome sequencing is being, and will continue to be, integrated into clinical care. In addition, the Commission heard from the patient advocacy communities who expressed their wishes for more participatory models of research.

About This Report

With its guiding principles in mind, the Commission sought to reconcile the anticipated societal benefit of the scientific and medical applications of advances in whole genome sequencing with the potential risks to individuals' privacy. Recognizing that our ethical obligations reach beyond what is legally enforceable, the Commission examined both the relevant ethical principles and the relevant legal requirements to offer guidance as to what (ethically) *ought* to be done and what (legally) *must* be done.³² This is the foundation upon which the Commission builds its recommendations, which apply to both the public and private sectors.

Accordingly, Section 1 deploys and applies the relevant ethical principles. Section 2 summarizes the legal framework governing whole genome sequencing and the legal protections provided for persons who decide to share their whole genome sequence data. Finally, Section 3 offers recommendations and guidelines that are aimed at reconciling the existing tension between minimizing risks to individuals and maximizing the anticipated future societal benefits of whole genome sequencing. The Commission intends that any changes resulting from these recommendations be prospective and not apply retrospectively to specimens already collected or stored in the research or clinical setting.

WORK OF PREVIOUS COMMISSIONS

Previous bioethics commissions have issued reports on topics related to genetics. In 1982, the President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research published a report, *Splicing Life*, which addressed the ethical and social implications of genetic engineering (<http://bioethics.georgetown.edu/documents/pcemr/splicinglife.pdf>). In 1983, the same commission issued a report on the ethical, social, and legal implications of genetic screening, counseling, and education programs, titled *Screening and Counseling for Genetic Conditions* (http://bioethics.georgetown.edu/pcbe/reports/past_commissions/geneticscreening.pdf).

Genetic issues were not revisited until the National Bioethics Advisory Commission (NBAC) discussed the issue of human cloning in 1997, in its report *Cloning Human Beings* (<http://bioethics.georgetown.edu/nbac/pubs/cloning1/cloning.pdf>). In 1999, NBAC issued *Research Involving Human Biological Materials: Ethical Issues and Policy Guidance*, which focused on research involving human biological materials (<http://bioethics.georgetown.edu/nbac/hbm.pdf>).

In 2002, the President's Council on Bioethics took up the issue of human cloning in its report, *Human Cloning and Human Dignity: An Ethical Inquiry* (http://bioethics.georgetown.edu/pcbe/reports/cloningreport/pcbe_cloning_report.pdf). The Council also published *The Changing Moral Focus of Newborn Screening*, which sought to establish ethical principles to guide newborn genetic screening (http://bioethics.georgetown.edu/pcbe/reports/newborn_screening/Newborn_Screening_for_the_web.pdf).

SECTION 1. ETHICAL PRINCIPLES

Whole genome sequencing offers the promise of tremendous public benefit, and is expected to change substantially our ability to assess risk, diagnose, and treat disease. Achieving this public benefit requires that researchers have access to large amounts of whole genome sequence data and associated medical information to assess correlations between underlying genomic variants and expressed disease. While many of the potential benefits arising from whole genome sequencing will accrue to the broader public, the risks associated with collecting and sharing whole genome sequence data will be borne disproportionately by the individuals whose data are being shared.

Because whole genome sequencing begins with obtaining a sample from an individual, to reconcile anticipated public benefits with potential individual harms the Commission begins with the principle of respect for persons. Respect for persons is among the most enduring and widely accepted foundations for protecting individual privacy in the pursuit of public benefit, and it is well formulated in the *Belmont Report*, a declaration of ethical principles regarding research involving human participants.³³ Since biomedical science has evolved significantly since the *Belmont Report's* publication in 1979 from clinically focused research to research for public benefit, the Commission also applies five additional ethical principles which flow from the principle of respect for persons—as outlined in *New Directions: The Ethics of Synthetic Biology and Emerging Technologies*—to the field of whole genome sequencing.³⁴ These five principles—public beneficence, responsible stewardship, intellectual freedom and responsibility, democratic deliberation, and justice and fairness—apply well not only to

emerging biotechnologies, but also to scientific advancement and innovation generally. The Commission's five principles are thus a useful supplement to the Belmont principles for the purpose of assessing the ethics of whole genome sequencing.

"The state of technology is that data acquisition is now... relatively inexpensive, and while the free access to genetic data has many positive benefits, we need to represent, of course, the tension of that with all of the other personal privacy issues..."
